If the form of *resource_acquisition* is *local_variable_declaration* then the type of the *local_variable_declaration* must be either `dynamic` or a type that can be implicitly converted to `System.IDisposable`. If the form of *resource_acquisition* is *expression* then this expression must be implicitly convertible to `System.IDisposable`.

Local variables declared in a *resource_acquisition* are read-only, and must include an initializer. A compile-time error occurs if the embedded statement attempts to modify these local variables (via assignment or the `++` and `--` operators), take the address of them, or pass them as `ref` or `out` parameters.

A `using` statement is translated into three parts: acquisition, usage, and disposal. Usage of the resource is implicitly enclosed in a `try` statement that includes a `finally` clause. This `finally` clause disposes of the resource. If a `null` resource is acquired, then no call to `Dispose` is made, and no exception is thrown. If the resource is of type `dynamic` it is dynamically converted through an implicit dynamic conversion ([Implicit dynamic conversions](#)) to `IDisposable` during acquisition in order to ensure that the conversion is successful before the usage and disposal.

A `using` statement of the form

```
using (ResourceType resource = expression) statement
```

corresponds to one of three possible expansions. When `ResourceType` is a non-nullable value type, the expansion is

```

{
    ResourceType resource = expression;
    try {
        statement;
    }
    finally {
        ((IDisposable)resource).Dispose();
    }
}

```

Otherwise, when `ResourceType` is a nullable value type or a reference type other than `dynamic`, the expansion is

```

{
    ResourceType resource = expression;
    try {
        statement;
    }
    finally {
        if (resource != null) ((IDisposable)resource).Dispose();
    }
}

```

Otherwise, when `ResourceType` is `dynamic`, the expansion is

```

{
    ResourceType resource = expression;
    IDisposable d = (IDisposable)resource;
    try {
        statement;
    }
    finally {
        if (d != null) d.Dispose();
    }
}

```

In either expansion, the `resource` variable is read-only in the embedded statement, and the `d` variable is inaccessible in, and invisible to, the embedded statement.

An implementation is permitted to implement a given using-statement differently, e.g. for performance reasons, as long as the behavior is consistent with the above expansion.

A `using` statement of the form

```
using (expression) statement
```

has the same three possible expansions. In this case `ResourceType` is implicitly the compile-time type of the `expression`, if it has one. Otherwise the interface `IDisposable` itself is used as the `ResourceType`. The `resource` variable is inaccessible in, and invisible to, the embedded statement.

When a *resource_acquisition* takes the form of a *local_variable_declaration*, it is possible to acquire multiple resources of a given type. A `using` statement of the form

```
using (ResourceType r1 = e1, r2 = e2, ..., rN = eN) statement
```

is precisely equivalent to a sequence of nested `using` statements:

```

using (ResourceType r1 = e1)
    using (ResourceType r2 = e2)
        ...
            using (ResourceType rN = eN)
                statement

```

The example below creates a file named `log.txt` and writes two lines of text to the file. The example then opens that same file for reading and copies the contained lines of text to the console.

```

using System;
using System.IO;

class Test
{
    static void Main() {
        using (TextWriter w = File.CreateText("log.txt")) {
            w.WriteLine("This is line one");
            w.WriteLine("This is line two");
        }

        using (TextReader r = File.OpenText("log.txt")) {
            string s;
            while ((s = r.ReadLine()) != null) {
                Console.WriteLine(s);
            }
        }
    }
}

```

Since the `TextWriter` and `TextReader` classes implement the `IDisposable` interface, the example can use `using` statements to ensure that the underlying file is properly closed following the write or read operations.

The yield statement

The `yield` statement is used in an iterator block ([Blocks](#)) to yield a value to the enumerator object ([Enumerator objects](#)) or enumerable object ([Enumerable objects](#)) of an iterator or to signal the end of the iteration.

```

yield_statement
: 'yield' 'return' expression ';'
| 'yield' 'break' ';'
;

```

`yield` is not a reserved word; it has special meaning only when used immediately before a `return` or `break` keyword. In other contexts, `yield` can be used as an identifier.

There are several restrictions on where a `yield` statement can appear, as described in the following.

- It is a compile-time error for a `yield` statement (of either form) to appear outside a *method_body*, *operator_body* or *accessor_body*
- It is a compile-time error for a `yield` statement (of either form) to appear inside an anonymous function.
- It is a compile-time error for a `yield` statement (of either form) to appear in the `finally` clause of a `try` statement.
- It is a compile-time error for a `yield return` statement to appear anywhere in a `try` statement that contains any `catch` clauses.

The following example shows some valid and invalid uses of `yield` statements.

```

delegate IEnumerable<int> D();

IEnumerator<int> GetEnumerator() {
    try {
        yield return 1;           // Ok
        yield break;             // Ok
    }
    finally {
        yield return 2;          // Error, yield in finally
        yield break;             // Error, yield in finally
    }

    try {
        yield return 3;          // Error, yield return in try...catch
        yield break;             // Ok
    }
    catch {
        yield return 4;          // Error, yield return in try...catch
        yield break;             // Ok
    }

    D d = delegate {
        yield return 5;          // Error, yield in an anonymous function
    };
}

int MyMethod() {
    yield return 1;              // Error, wrong return type for an iterator block
}

```

An implicit conversion ([Implicit conversions](#)) must exist from the type of the expression in the `yield return` statement to the yield type ([Yield type](#)) of the iterator.

A `yield return` statement is executed as follows:

- The expression given in the statement is evaluated, implicitly converted to the yield type, and assigned to the `Current` property of the enumerator object.
- Execution of the iterator block is suspended. If the `yield return` statement is within one or more `try` blocks, the associated `finally` blocks are not executed at this time.
- The `MoveNext` method of the enumerator object returns `true` to its caller, indicating that the enumerator object successfully advanced to the next item.

The next call to the enumerator object's `MoveNext` method resumes execution of the iterator block from where it was last suspended.

A `yield break` statement is executed as follows:

- If the `yield break` statement is enclosed by one or more `try` blocks with associated `finally` blocks, control is initially transferred to the `finally` block of the innermost `try` statement. When and if control reaches the end point of a `finally` block, control is transferred to the `finally` block of the next enclosing `try` statement. This process is repeated until the `finally` blocks of all enclosing `try` statements have been executed.
- Control is returned to the caller of the iterator block. This is either the `MoveNext` method or `Dispose` method of the enumerator object.

Because a `yield break` statement unconditionally transfers control elsewhere, the end point of a `yield break` statement is never reachable.

Namespaces

12/28/2021 • 18 minutes to read • [Edit Online](#)

C# programs are organized using namespaces. Namespaces are used both as an "internal" organization system for a program, and as an "external" organization system—a way of presenting program elements that are exposed to other programs.

Using directives ([Using directives](#)) are provided to facilitate the use of namespaces.

Compilation units

A *compilation_unit* defines the overall structure of a source file. A compilation unit consists of zero or more *using_directives* followed by zero or more *global_attributes* followed by zero or more *namespace_member_declarations*.

```
compilation_unit
: extern_alias_directive* using_directive* global_attributes? namespace_member_declaration*
;
```

A C# program consists of one or more compilation units, each contained in a separate source file. When a C# program is compiled, all of the compilation units are processed together. Thus, compilation units can depend on each other, possibly in a circular fashion.

The *using_directives* of a compilation unit affect the *global_attributes* and *namespace_member_declarations* of that compilation unit, but have no effect on other compilation units.

The *global_attributes* ([Attributes](#)) of a compilation unit permit the specification of attributes for the target assembly and module. Assemblies and modules act as physical containers for types. An assembly may consist of several physically separate modules.

The *namespace_member_declarations* of each compilation unit of a program contribute members to a single declaration space called the global namespace. For example:

File `A.cs`:

```
class A {}
```

File `B.cs`:

```
class B {}
```

The two compilation units contribute to the single global namespace, in this case declaring two classes with the fully qualified names `A` and `B`. Because the two compilation units contribute to the same declaration space, it would have been an error if each contained a declaration of a member with the same name.

Namespace declarations

A *namespace_declaration* consists of the keyword `namespace`, followed by a namespace name and body, optionally followed by a semicolon.

```

namespace_declaration
    : 'namespace' qualified_identifier namespace_body ';' '?'
    ;

qualified_identifier
    : identifier ('.' identifier)*
    ;

namespace_body
    : '{' extern_alias_directive* using_directive* namespace_member_declaration* '}'
    ;

```

A *namespace_declaration* may occur as a top-level declaration in a *compilation_unit* or as a member declaration within another *namespace_declaration*. When a *namespace_declaration* occurs as a top-level declaration in a *compilation_unit*, the namespace becomes a member of the global namespace. When a *namespace_declaration* occurs within another *namespace_declaration*, the inner namespace becomes a member of the outer namespace. In either case, the name of a namespace must be unique within the containing namespace.

Namespaces are implicitly `public` and the declaration of a namespace cannot include any access modifiers.

Within a *namespace_body*, the optional *using_directives* import the names of other namespaces, types and members, allowing them to be referenced directly instead of through qualified names. The optional *namespace_member_declarations* contribute members to the declaration space of the namespace. Note that all *using_directives* must appear before any member declarations.

The *qualified_identifier* of a *namespace_declaration* may be a single identifier or a sequence of identifiers separated by "." tokens. The latter form permits a program to define a nested namespace without lexically nesting several namespace declarations. For example,

```

namespace N1.N2
{
    class A {}

    class B {}
}

```

is semantically equivalent to

```

namespace N1
{
    namespace N2
    {
        class A {}

        class B {}
    }
}

```

Namespaces are open-ended, and two namespace declarations with the same fully qualified name contribute to the same declaration space ([Declarations](#)). In the example

```

namespace N1.N2
{
    class A {}
}

namespace N1.N2
{
    class B {}
}

```

the two namespace declarations above contribute to the same declaration space, in this case declaring two classes with the fully qualified names `N1.N2.A` and `N1.N2.B`. Because the two declarations contribute to the same declaration space, it would have been an error if each contained a declaration of a member with the same name.

Extern aliases

An *extern_alias_directive* introduces an identifier that serves as an alias for a namespace. The specification of the aliased namespace is external to the source code of the program and applies also to nested namespaces of the aliased namespace.

```

extern_alias_directive
: 'extern' 'alias' identifier ';'
;

```

The scope of an *extern_alias_directive* extends over the *using_directives*, *global_attributes* and *namespace_member_declarations* of its immediately containing compilation unit or namespace body.

Within a compilation unit or namespace body that contains an *extern_alias_directive*, the identifier introduced by the *extern_alias_directive* can be used to reference the aliased namespace. It is a compile-time error for the *identifier* to be the word `global`.

An *extern_alias_directive* makes an alias available within a particular compilation unit or namespace body, but it does not contribute any new members to the underlying declaration space. In other words, an *extern_alias_directive* is not transitive, but, rather, affects only the compilation unit or namespace body in which it occurs.

The following program declares and uses two extern aliases, `x` and `y`, each of which represent the root of a distinct namespace hierarchy:

```

extern alias X;
extern alias Y;

class Test
{
    X::N.A a;
    X::N.B b1;
    Y::N.B b2;
    Y::N.C c;
}

```

The program declares the existence of the extern aliases `x` and `y`, but the actual definitions of the aliases are external to the program. The identically named `N.B` classes can now be referenced as `x.N.B` and `y.N.B`, or, using the namespace alias qualifier, `x::N.B` and `y::N.B`. An error occurs if a program declares an extern alias for which no external definition is provided.

Using directives

Using directives facilitate the use of namespaces and types defined in other namespaces. Using directives impact the name resolution process of *namespace_or_type_names* ([Namespace and type names](#)) and *simple_names* ([Simple names](#)), but unlike declarations, using directives do not contribute new members to the underlying declaration spaces of the compilation units or namespaces within which they are used.

```
using_directive
: using_alias_directive
| using_namespace_directive
| using_static_directive
;
```

A *using_alias_directive* ([Using alias directives](#)) introduces an alias for a namespace or type.

A *using_namespace_directive* ([Using namespace directives](#)) imports the type members of a namespace.

A *using_static_directive* ([Using static directives](#)) imports the nested types and static members of a type.

The scope of a *using_directive* extends over the *namespace_member_declarations* of its immediately containing compilation unit or namespace body. The scope of a *using_directive* specifically does not include its peer *using_directives*. Thus, peer *using_directives* do not affect each other, and the order in which they are written is insignificant.

Using alias directives

A *using_alias_directive* introduces an identifier that serves as an alias for a namespace or type within the immediately enclosing compilation unit or namespace body.

```
using_alias_directive
: 'using' identifier '=' namespace_or_type_name ';'
;
```

Within member declarations in a compilation unit or namespace body that contains a *using_alias_directive*, the identifier introduced by the *using_alias_directive* can be used to reference the given namespace or type. For example:

```
namespace N1.N2
{
    class A {}
}

namespace N3
{
    using A = N1.N2.A;

    class B: A {}
}
```

Above, within member declarations in the `N3` namespace, `A` is an alias for `N1.N2.A`, and thus class `N3.B` derives from class `N1.N2.A`. The same effect can be obtained by creating an alias `R` for `N1.N2` and then referencing `R.A`:

```

namespace N3
{
    using R = N1.N2;

    class B: R.A {}
}

```

The *identifier* of a *using_alias_directive* must be unique within the declaration space of the compilation unit or namespace that immediately contains the *using_alias_directive*. For example:

```

namespace N3
{
    class A {}
}

namespace N3
{
    using A = N1.N2.A;      // Error, A already exists
}

```

Above, `N3` already contains a member `A`, so it is a compile-time error for a *using_alias_directive* to use that identifier. Likewise, it is a compile-time error for two or more *using_alias_directives* in the same compilation unit or namespace body to declare aliases by the same name.

A *using_alias_directive* makes an alias available within a particular compilation unit or namespace body, but it does not contribute any new members to the underlying declaration space. In other words, a *using_alias_directive* is not transitive but rather affects only the compilation unit or namespace body in which it occurs. In the example

```

namespace N3
{
    using R = N1.N2;
}

namespace N3
{
    class B: R.A {}          // Error, R unknown
}

```

the scope of the *using_alias_directive* that introduces `R` only extends to member declarations in the namespace body in which it is contained, so `R` is unknown in the second namespace declaration. However, placing the *using_alias_directive* in the containing compilation unit causes the alias to become available within both namespace declarations:

```

using R = N1.N2;

namespace N3
{
    class B: R.A {}
}

namespace N3
{
    class C: R.A {}
}

```

Just like regular members, names introduced by *using_alias_directives* are hidden by similarly named members in nested scopes. In the example

```

using R = N1.N2;

namespace N3
{
    class R {}

    class B: R.A {}          // Error, R has no member A
}

```

the reference to `R.A` in the declaration of `B` causes a compile-time error because `R` refers to `N3.R`, not `N1.N2`.

The order in which *using_alias_directives* are written has no significance, and resolution of the *namespace_or_type_name* referenced by a *using_alias_directive* is not affected by the *using_alias_directive* itself or by other *using_directives* in the immediately containing compilation unit or namespace body. In other words, the *namespace_or_type_name* of a *using_alias_directive* is resolved as if the immediately containing compilation unit or namespace body had no *using_directives*. A *using_alias_directive* may however be affected by *extern_alias_directives* in the immediately containing compilation unit or namespace body. In the example

```

namespace N1.N2 {}

namespace N3
{
    extern alias E;

    using R1 = E.N;          // OK

    using R2 = N1;           // OK

    using R3 = N1.N2;        // OK

    using R4 = R2.N2;        // Error, R2 unknown
}

```

the last *using_alias_directive* results in a compile-time error because it is not affected by the first *using_alias_directive*. The first *using_alias_directive* does not result in an error since the scope of the extern alias `E` includes the *using_alias_directive*.

A *using_alias_directive* can create an alias for any namespace or type, including the namespace within which it appears and any namespace or type nested within that namespace.

Accessing a namespace or type through an alias yields exactly the same result as accessing that namespace or type through its declared name. For example, given

```

namespace N1.N2
{
    class A {}
}

namespace N3
{
    using R1 = N1;
    using R2 = N1.N2;

    class B
    {
        N1.N2.A a;           // refers to N1.N2.A
        R1.N2.A b;           // refers to N1.N2.A
        R2.A c;              // refers to N1.N2.A
    }
}

```

the names `N1.N2.A`, `R1.N2.A`, and `R2.A` are equivalent and all refer to the class whose fully qualified name is `N1.N2.A`.

Using aliases can name a closed constructed type, but cannot name an unbound generic type declaration without supplying type arguments. For example:

```

namespace N1
{
    class A<T>
    {
        class B {}
    }
}

namespace N2
{
    using W = N1.A;           // Error, cannot name unbound generic type

    using X = N1.A.B;         // Error, cannot name unbound generic type

    using Y = N1.A<int>;      // Ok, can name closed constructed type

    using Z<T> = N1.A<T>;     // Error, using alias cannot have type parameters
}

```

Using namespace directives

A *using_namespace_directive* imports the types contained in a namespace into the immediately enclosing compilation unit or namespace body, enabling the identifier of each type to be used without qualification.

```

using_namespace_directive
: 'using' namespace_name ';'
;

```

Within member declarations in a compilation unit or namespace body that contains a *using_namespace_directive*, the types contained in the given namespace can be referenced directly. For example:

```

namespace N1.N2
{
    class A {}
}

namespace N3
{
    using N1.N2;

    class B: A {}
}

```

Above, within member declarations in the `N3` namespace, the type members of `N1.N2` are directly available, and thus class `N3.B` derives from class `N1.N2.A`.

A *using_namespace_directive* imports the types contained in the given namespace, but specifically does not import nested namespaces. In the example

```

namespace N1.N2
{
    class A {}
}

namespace N3
{
    using N1;

    class B: N2.A {}      // Error, N2 unknown
}

```

the *using_namespace_directive* imports the types contained in `N1`, but not the namespaces nested in `N1`. Thus, the reference to `N2.A` in the declaration of `B` results in a compile-time error because no members named `N2` are in scope.

Unlike a *using_alias_directive*, a *using_namespace_directive* may import types whose identifiers are already defined within the enclosing compilation unit or namespace body. In effect, names imported by a *using_namespace_directive* are hidden by similarly named members in the enclosing compilation unit or namespace body. For example:

```

namespace N1.N2
{
    class A {}

    class B {}
}

namespace N3
{
    using N1.N2;

    class A {}
}

```

Here, within member declarations in the `N3` namespace, `A` refers to `N3.A` rather than `N1.N2.A`.

When more than one namespace or type imported by *using_namespace_directives* or *using_static_directives* in the same compilation unit or namespace body contain types by the same name, references to that name as a *type_name* are considered ambiguous. In the example

```

namespace N1
{
    class A {}
}

namespace N2
{
    class A {}
}

namespace N3
{
    using N1;

    using N2;

    class B: A {}           // Error, A is ambiguous
}

```

both `N1` and `N2` contain a member `A`, and because `N3` imports both, referencing `A` in `N3` is a compile-time error. In this situation, the conflict can be resolved either through qualification of references to `A`, or by introducing a *using_alias_directive* that picks a particular `A`. For example:

```

namespace N3
{
    using N1;

    using N2;

    using A = N1.A;

    class B: A {}           // A means N1.A
}

```

Furthermore, when more than one namespace or type imported by *using_namespace_directives* or *using_static_directives* in the same compilation unit or namespace body contain types or members by the same name, references to that name as a *simple_name* are considered ambiguous. In the example

```

namespace N1
{
    class A {}
}

class C
{
    public static int A;
}

namespace N2
{
    using N1;
    using static C;

    class B
    {
        void M()
        {
            A a = new A();    // Ok, A is unambiguous as a type-name
            A.Equals(2);      // Error, A is ambiguous as a simple-name
        }
    }
}

```

`N1` contains a type member `A`, and `C` contains a static field `A`, and because `N2` imports both, referencing `A` as a *simple_name* is ambiguous and a compile-time error.

Like a *using_alias_directive*, a *using_namespace_directive* does not contribute any new members to the underlying declaration space of the compilation unit or namespace, but rather affects only the compilation unit or namespace body in which it appears.

The *namespace_name* referenced by a *using_namespace_directive* is resolved in the same way as the *namespace_or_type_name* referenced by a *using_alias_directive*. Thus, *using_namespace_directives* in the same compilation unit or namespace body do not affect each other and can be written in any order.

Using static directives

A *using_static_directive* imports the nested types and static members contained directly in a type declaration into the immediately enclosing compilation unit or namespace body, enabling the identifier of each member and type to be used without qualification.

```

using_static_directive
    : 'using' 'static' type_name ';'
    ;

```

Within member declarations in a compilation unit or namespace body that contains a *using_static_directive*, the accessible nested types and static members (except extension methods) contained directly in the declaration of the given type can be referenced directly. For example:

```

namespace N1
{
    class A
    {
        public class B{}
        public static B M(){ return new B(); }
    }
}

namespace N2
{
    using static N1.A;
    class C
    {
        void N() { B b = M(); }
    }
}

```

Above, within member declarations in the `N2` namespace, the static members and nested types of `N1.A` are directly available, and thus the method `N` is able to reference both the `B` and `M` members of `N1.A`.

A *using_static_directive* specifically does not import extension methods directly as static methods, but makes them available for extension method invocation ([Extension method invocations](#)). In the example

```

namespace N1
{
    static class A
    {
        public static void M(this string s){}
    }
}

namespace N2
{
    using static N1.A;

    class B
    {
        void N()
        {
            M("A");      // Error, M unknown
            "B".M();      // Ok, M known as extension method
            N1.A.M("C"); // Ok, fully qualified
        }
    }
}

```

the *using_static_directive* imports the extension method `M` contained in `N1.A`, but only as an extension method. Thus, the first reference to `M` in the body of `B.N` results in a compile-time error because no members named `M` are in scope.

A *using_static_directive* only imports members and types declared directly in the given type, not members and types declared in base classes.

TODO: Example

Ambiguities between multiple *using_namespace_directives* and *using_static_directives* are discussed in [Using namespace directives](#).

Namespace members

A *namespace_member_declaration* is either a *namespace_declaration* ([Namespace declarations](#)) or a *type_declaration* ([Type declarations](#)).

```
namespace_member_declaration
: namespace_declaration
| type_declaration
;
```

A compilation unit or a namespace body can contain *namespace_member_declarations*, and such declarations contribute new members to the underlying declaration space of the containing compilation unit or namespace body.

Type declarations

A *type_declaration* is a *class_declaration* ([Class declarations](#)), a *struct_declaration* ([Struct declarations](#)), an *interface_declaration* ([Interface declarations](#)), an *enum_declaration* ([Enum declarations](#)), or a *delegate_declaration* ([Delegate declarations](#)).

```
type_declaration
: class_declaration
| struct_declaration
| interface_declaration
| enum_declaration
| delegate_declaration
;
```

A *type_declaration* can occur as a top-level declaration in a compilation unit or as a member declaration within a namespace, class, or struct.

When a type declaration for a type `T` occurs as a top-level declaration in a compilation unit, the fully qualified name of the newly declared type is simply `T`. When a type declaration for a type `T` occurs within a namespace, class, or struct, the fully qualified name of the newly declared type is `N.T`, where `N` is the fully qualified name of the containing namespace, class, or struct.

A type declared within a class or struct is called a nested type ([Nested types](#)).

The permitted access modifiers and the default access for a type declaration depend on the context in which the declaration takes place ([Declared accessibility](#)):

- Types declared in compilation units or namespaces can have `public` or `internal` access. The default is `internal` access.
- Types declared in classes can have `public`, `protected internal`, `protected`, `internal`, or `private` access. The default is `private` access.
- Types declared in structs can have `public`, `internal`, or `private` access. The default is `private` access.

Namespace alias qualifiers

The *namespace alias qualifier* `::` makes it possible to guarantee that type name lookups are unaffected by the introduction of new types and members. The namespace alias qualifier always appears between two identifiers referred to as the left-hand and right-hand identifiers. Unlike the regular `.` qualifier, the left-hand identifier of the `::` qualifier is looked up only as an extern or using alias.

A *qualified_alias_member* is defined as follows:

```
qualified_alias_member
: identifier '::' identifier type_argument_list?
;
```

A *qualified_alias_member* can be used as a *namespace_or_type_name* ([Namespace and type names](#)) or as the left operand in a *member_access* ([Member access](#)).

A *qualified_alias_member* has one of two forms:

- $N::I\langle A_1, \dots, A_k \rangle$, where N and I represent identifiers, and $\langle A_1, \dots, A_k \rangle$ is a type argument list. (k is always at least one.)
- $N::I$, where N and I represent identifiers. (In this case, k is considered to be zero.)

Using this notation, the meaning of a *qualified_alias_member* is determined as follows:

- If N is the identifier `global`, then the global namespace is searched for I :
 - If the global namespace contains a namespace named I and k is zero, then the *qualified_alias_member* refers to that namespace.
 - Otherwise, if the global namespace contains a non-generic type named I and k is zero, then the *qualified_alias_member* refers to that type.
 - Otherwise, if the global namespace contains a type named I that has k type parameters, then the *qualified_alias_member* refers to that type constructed with the given type arguments.
 - Otherwise, the *qualified_alias_member* is undefined and a compile-time error occurs.
- Otherwise, starting with the namespace declaration ([Namespace declarations](#)) immediately containing the *qualified_alias_member* (if any), continuing with each enclosing namespace declaration (if any), and ending with the compilation unit containing the *qualified_alias_member*, the following steps are evaluated until an entity is located:
 - If the namespace declaration or compilation unit contains a *using_alias_directive* that associates N with a type, then the *qualified_alias_member* is undefined and a compile-time error occurs.
 - Otherwise, if the namespace declaration or compilation unit contains an *extern_alias_directive* or *using_alias_directive* that associates N with a namespace, then:
 - If the namespace associated with N contains a namespace named I and k is zero, then the *qualified_alias_member* refers to that namespace.
 - Otherwise, if the namespace associated with N contains a non-generic type named I and k is zero, then the *qualified_alias_member* refers to that type.
 - Otherwise, if the namespace associated with N contains a type named I that has k type parameters, then the *qualified_alias_member* refers to that type constructed with the given type arguments.
 - Otherwise, the *qualified_alias_member* is undefined and a compile-time error occurs.
- Otherwise, the *qualified_alias_member* is undefined and a compile-time error occurs.

Note that using the namespace alias qualifier with an alias that references a type causes a compile-time error. Also note that if the identifier N is `global`, then lookup is performed in the global namespace, even if there is a using alias associating `global` with a type or namespace.

Uniqueness of aliases

Each compilation unit and namespace body has a separate declaration space for extern aliases and using aliases. Thus, while the name of an extern alias or using alias must be unique within the set of extern aliases and using aliases declared in the immediately containing compilation unit or namespace body, an alias is permitted to have the same name as a type or namespace as long as it is used only with the `::` qualifier.

In the example

```
namespace N
{
    public class A {}

    public class B {}
}

namespace N
{
    using A = System.IO;

    class X
    {
        A.Stream s1;           // Error, A is ambiguous

        A::Stream s2;         // Ok
    }
}
```

the name `A` has two possible meanings in the second namespace body because both the class `A` and the using alias `A` are in scope. For this reason, use of `A` in the qualified name `A.Stream` is ambiguous and causes a compile-time error to occur. However, use of `A` with the `::` qualifier is not an error because `A` is looked up only as a namespace alias.

Classes

12/28/2021 • 170 minutes to read • [Edit Online](#)

A class is a data structure that may contain data members (constants and fields), function members (methods, properties, events, indexers, operators, instance constructors, destructors and static constructors), and nested types. Class types support inheritance, a mechanism whereby a derived class can extend and specialize a base class.

Class declarations

A *class_declaration* is a *type_declaration* ([Type declarations](#)) that declares a new class.

```
class_declaration
: attributes? class_modifier* 'partial'? 'class' identifier type_parameter_list?
  class_base? type_parameter_constraints_clause* class_body ';'?
```

A *class_declaration* consists of an optional set of *attributes* ([Attributes](#)), followed by an optional set of *class_modifiers* ([Class modifiers](#)), followed by an optional `partial` modifier, followed by the keyword `class` and an *identifier* that names the class, followed by an optional *type_parameter_list* ([Type parameters](#)), followed by an optional *class_base* specification ([Class base specification](#)), followed by an optional set of *type_parameter_constraints_clauses* ([Type parameter constraints](#)), followed by a *class_body* ([Class body](#)), optionally followed by a semicolon.

A class declaration cannot supply *type_parameter_constraints_clauses* unless it also supplies a *type_parameter_list*.

A class declaration that supplies a *type_parameter_list* is a **generic class declaration**. Additionally, any class nested inside a generic class declaration or a generic struct declaration is itself a generic class declaration, since type parameters for the containing type must be supplied to create a constructed type.

Class modifiers

A *class_declaration* may optionally include a sequence of class modifiers:

```
class_modifier
: 'new'
| 'public'
| 'protected'
| 'internal'
| 'private'
| 'abstract'
| 'sealed'
| 'static'
| class_modifier_unsafe
```

It is a compile-time error for the same modifier to appear multiple times in a class declaration.

The `new` modifier is permitted on nested classes. It specifies that the class hides an inherited member by the same name, as described in [The new modifier](#). It is a compile-time error for the `new` modifier to appear on a class declaration that is not a nested class declaration.

The `public`, `protected`, `internal`, and `private` modifiers control the accessibility of the class. Depending on

the context in which the class declaration occurs, some of these modifiers may not be permitted ([Declared accessibility](#)).

The `abstract`, `sealed` and `static` modifiers are discussed in the following sections.

Abstract classes

The `abstract` modifier is used to indicate that a class is incomplete and that it is intended to be used only as a base class. An abstract class differs from a non-abstract class in the following ways:

- An abstract class cannot be instantiated directly, and it is a compile-time error to use the `new` operator on an abstract class. While it is possible to have variables and values whose compile-time types are abstract, such variables and values will necessarily either be `null` or contain references to instances of non-abstract classes derived from the abstract types.
- An abstract class is permitted (but not required) to contain abstract members.
- An abstract class cannot be sealed.

When a non-abstract class is derived from an abstract class, the non-abstract class must include actual implementations of all inherited abstract members, thereby overriding those abstract members. In the example

```
abstract class A
{
    public abstract void F();
}

abstract class B: A
{
    public void G() {}
}

class C: B
{
    public override void F() {
        // actual implementation of F
    }
}
```

the abstract class `A` introduces an abstract method `F`. Class `B` introduces an additional method `G`, but since it doesn't provide an implementation of `F`, `B` must also be declared abstract. Class `C` overrides `F` and provides an actual implementation. Since there are no abstract members in `C`, `C` is permitted (but not required) to be non-abstract.

Sealed classes

The `sealed` modifier is used to prevent derivation from a class. A compile-time error occurs if a sealed class is specified as the base class of another class.

A sealed class cannot also be an abstract class.

The `sealed` modifier is primarily used to prevent unintended derivation, but it also enables certain run-time optimizations. In particular, because a sealed class is known to never have any derived classes, it is possible to transform virtual function member invocations on sealed class instances into non-virtual invocations.

Static classes

The `static` modifier is used to mark the class being declared as a *static class*. A static class cannot be instantiated, cannot be used as a type and can contain only static members. Only a static class can contain declarations of extension methods ([Extension methods](#)).

A static class declaration is subject to the following restrictions:

- A static class may not include a `sealed` or `abstract` modifier. Note, however, that since a static class cannot

be instantiated or derived from, it behaves as if it was both sealed and abstract.

- A static class may not include a *class_base* specification ([Class base specification](#)) and cannot explicitly specify a base class or a list of implemented interfaces. A static class implicitly inherits from type `object`.
- A static class can only contain static members ([Static and instance members](#)). Note that constants and nested types are classified as static members.
- A static class cannot have members with `protected` or `protected internal` declared accessibility.

It is a compile-time error to violate any of these restrictions.

A static class has no instance constructors. It is not possible to declare an instance constructor in a static class, and no default instance constructor ([Default constructors](#)) is provided for a static class.

The members of a static class are not automatically static, and the member declarations must explicitly include a `static` modifier (except for constants and nested types). When a class is nested within a static outer class, the nested class is not a static class unless it explicitly includes a `static` modifier.

Referencing static class types

A *namespace_or_type_name* ([Namespace and type names](#)) is permitted to reference a static class if

- The *namespace_or_type_name* is the `T` in a *namespace_or_type_name* of the form `T.I`, or
- The *namespace_or_type_name* is the `T` in a *typeof_expression* ([Argument lists](#)¹) of the form `typeof(T)`.

A *primary_expression* ([Function members](#)) is permitted to reference a static class if

- The *primary_expression* is the `E` in a *member_access* ([Compile-time checking of dynamic overload resolution](#)) of the form `E.I`.

In any other context it is a compile-time error to reference a static class. For example, it is an error for a static class to be used as a base class, a constituent type ([Nested types](#)) of a member, a generic type argument, or a type parameter constraint. Likewise, a static class cannot be used in an array type, a pointer type, a `new` expression, a cast expression, an `is` expression, an `as` expression, a `sizeof` expression, or a default value expression.

Partial modifier

The `partial` modifier is used to indicate that this *class_declaration* is a partial type declaration. Multiple partial type declarations with the same name within an enclosing namespace or type declaration combine to form one type declaration, following the rules specified in [Partial types](#).

Having the declaration of a class distributed over separate segments of program text can be useful if these segments are produced or maintained in different contexts. For instance, one part of a class declaration may be machine generated, whereas the other is manually authored. Textual separation of the two prevents updates by one from conflicting with updates by the other.

Type parameters

A type parameter is a simple identifier that denotes a placeholder for a type argument supplied to create a constructed type. A type parameter is a formal placeholder for a type that will be supplied later. By contrast, a type argument ([Type arguments](#)) is the actual type that is substituted for the type parameter when a constructed type is created.

```

type_parameter_list
: '<' type_parameters '>'
;

type_parameters
: attributes? type_parameter
| type_parameters ',' attributes? type_parameter
;

type_parameter
: identifier
;

```

Each type parameter in a class declaration defines a name in the declaration space ([Declarations](#)) of that class. Thus, it cannot have the same name as another type parameter or a member declared in that class. A type parameter cannot have the same name as the type itself.

Class base specification

A class declaration may include a *class_base* specification, which defines the direct base class of the class and the interfaces ([Interfaces](#)) directly implemented by the class.

```

class_base
: ':' class_type
| ':' interface_type_list
| ':' class_type ',' interface_type_list
;

interface_type_list
: interface_type (',' interface_type)*
;

```

The base class specified in a class declaration can be a constructed class type ([Constructed types](#)). A base class cannot be a type parameter on its own, though it can involve the type parameters that are in scope.

```

class Extend<V>: V {}           // Error, type parameter used as base class

```

Base classes

When a *class_type* is included in the *class_base*, it specifies the direct base class of the class being declared. If a class declaration has no *class_base*, or if the *class_base* lists only interface types, the direct base class is assumed to be `object`. A class inherits members from its direct base class, as described in [Inheritance](#).

In the example

```

class A {}

class B: A {}

```

class `A` is said to be the direct base class of `B`, and `B` is said to be derived from `A`. Since `A` does not explicitly specify a direct base class, its direct base class is implicitly `object`.

For a constructed class type, if a base class is specified in the generic class declaration, the base class of the constructed type is obtained by substituting, for each *type_parameter* in the base class declaration, the corresponding *type_argument* of the constructed type. Given the generic class declarations

```
class B<U,V> {...}

class G<T>: B<string,T[]> {...}
```

the base class of the constructed type `G<int>` would be `B<string,int[]>`.

The direct base class of a class type must be at least as accessible as the class type itself ([Accessibility domains](#)). For example, it is a compile-time error for a `public` class to derive from a `private` or `internal` class.

The direct base class of a class type must not be any of the following types: `System.Array`, `System.Delegate`, `System.MulticastDelegate`, `System.Enum`, or `System.ValueType`. Furthermore, a generic class declaration cannot use `System.Attribute` as a direct or indirect base class.

While determining the meaning of the direct base class specification `A` of a class `B`, the direct base class of `B` is temporarily assumed to be `object`. Intuitively this ensures that the meaning of a base class specification cannot recursively depend on itself. The example:

```
class A<T> {
    public class B {}
}

class C : A<C.B> {}
```

is in error since in the base class specification `A<C.B>` the direct base class of `C` is considered to be `object`, and hence (by the rules of [Namespace and type names](#)) `C` is not considered to have a member `B`.

The base classes of a class type are the direct base class and its base classes. In other words, the set of base classes is the transitive closure of the direct base class relationship. Referring to the example above, the base classes of `B` are `A` and `object`. In the example

```
class A {...}

class B<T>: A {...}

class C<T>: B<IComparable<T>> {...}

class D<T>: C<T[]> {...}
```

the base classes of `D<int>` are `C<int[]>`, `B<IComparable<int[]>>`, `A`, and `object`.

Except for class `object`, every class type has exactly one direct base class. The `object` class has no direct base class and is the ultimate base class of all other classes.

When a class `B` derives from a class `A`, it is a compile-time error for `A` to depend on `B`. A class **directly depends on** its direct base class (if any) and **directly depends on** the class within which it is immediately nested (if any). Given this definition, the complete set of classes upon which a class depends is the reflexive and transitive closure of the **directly depends on** relationship.

The example

```
class A: A {}
```

is erroneous because the class depends on itself. Likewise, the example

```
class A: B {}
class B: C {}
class C: A {}
```

is in error because the classes circularly depend on themselves. Finally, the example

```
class A: B.C {}

class B: A
{
    public class C {}
}
```

results in a compile-time error because `A` depends on `B.C` (its direct base class), which depends on `B` (its immediately enclosing class), which circularly depends on `A`.

Note that a class does not depend on the classes that are nested within it. In the example

```
class A
{
    class B: A {}
}
```

`B` depends on `A` (because `A` is both its direct base class and its immediately enclosing class), but `A` does not depend on `B` (since `B` is neither a base class nor an enclosing class of `A`). Thus, the example is valid.

It is not possible to derive from a `sealed` class. In the example

```
sealed class A {}

class B: A {}           // Error, cannot derive from a sealed class
```

class `B` is in error because it attempts to derive from the `sealed` class `A`.

Interface implementations

A *class_base* specification may include a list of interface types, in which case the class is said to directly implement the given interface types. Interface implementations are discussed further in [Interface implementations](#).

Type parameter constraints

Generic type and method declarations can optionally specify type parameter constraints by including *type_parameter_constraints_clauses*.

```

type_parameter_constraints_clause
: 'where' type_parameter ':' type_parameter_constraints
;

type_parameter_constraints
: primary_constraint
| secondary_constraints
| constructor_constraint
| primary_constraint ',' secondary_constraints
| primary_constraint ',' constructor_constraint
| secondary_constraints ',' constructor_constraint
| primary_constraint ',' secondary_constraints ',' constructor_constraint
;

primary_constraint
: class_type
| 'class'
| 'struct'
;

secondary_constraints
: interface_type
| type_parameter
| secondary_constraints ',' interface_type
| secondary_constraints ',' type_parameter
;

constructor_constraint
: 'new' '(' ')'
;

```

Each *type_parameter_constraints_clause* consists of the token `where`, followed by the name of a type parameter, followed by a colon and the list of constraints for that type parameter. There can be at most one `where` clause for each type parameter, and the `where` clauses can be listed in any order. Like the `get` and `set` tokens in a property accessor, the `where` token is not a keyword.

The list of constraints given in a `where` clause can include any of the following components, in this order: a single primary constraint, one or more secondary constraints, and the constructor constraint, `new()`.

A primary constraint can be a class type or the *reference type constraint* `class` or the *value type constraint* `struct`. A secondary constraint can be a *type_parameter* or *interface_type*.

The reference type constraint specifies that a type argument used for the type parameter must be a reference type. All class types, interface types, delegate types, array types, and type parameters known to be a reference type (as defined below) satisfy this constraint.

The value type constraint specifies that a type argument used for the type parameter must be a non-nullable value type. All non-nullable struct types, enum types, and type parameters having the value type constraint satisfy this constraint. Note that although classified as a value type, a nullable type ([Nullable types](#)) does not satisfy the value type constraint. A type parameter having the value type constraint cannot also have the *constructor_constraint*.

Pointer types are never allowed to be type arguments and are not considered to satisfy either the reference type or value type constraints.

If a constraint is a class type, an interface type, or a type parameter, that type specifies a minimal "base type" that every type argument used for that type parameter must support. Whenever a constructed type or generic method is used, the type argument is checked against the constraints on the type parameter at compile-time. The type argument supplied must satisfy the conditions described in [Satisfying constraints](#).

A *class_type* constraint must satisfy the following rules:

- The type must be a class type.
- The type must not be `sealed`.
- The type must not be one of the following types: `System.Array`, `System.Delegate`, `System.Enum`, or `System.ValueType`.
- The type must not be `object`. Because all types derive from `object`, such a constraint would have no effect if it were permitted.
- At most one constraint for a given type parameter can be a class type.

A type specified as an *interface_type* constraint must satisfy the following rules:

- The type must be an interface type.
- A type must not be specified more than once in a given `where` clause.

In either case, the constraint can involve any of the type parameters of the associated type or method declaration as part of a constructed type, and can involve the type being declared.

Any class or interface type specified as a type parameter constraint must be at least as accessible ([Accessibility constraints](#)) as the generic type or method being declared.

A type specified as a *type_parameter* constraint must satisfy the following rules:

- The type must be a type parameter.
- A type must not be specified more than once in a given `where` clause.

In addition there must be no cycles in the dependency graph of type parameters, where dependency is a transitive relation defined by:

- If a type parameter `T` is used as a constraint for type parameter `S` then `S` **depends on** `T`.
- If a type parameter `S` depends on a type parameter `T` and `T` depends on a type parameter `U` then `S` **depends on** `U`.

Given this relation, it is a compile-time error for a type parameter to depend on itself (directly or indirectly).

Any constraints must be consistent among dependent type parameters. If type parameter `S` depends on type parameter `T` then:

- `T` must not have the value type constraint. Otherwise, `T` is effectively sealed so `S` would be forced to be the same type as `T`, eliminating the need for two type parameters.
- If `S` has the value type constraint then `T` must not have a *class_type* constraint.
- If `S` has a *class_type* constraint `A` and `T` has a *class_type* constraint `B` then there must be an identity conversion or implicit reference conversion from `A` to `B` or an implicit reference conversion from `B` to `A`.
- If `S` also depends on type parameter `U` and `U` has a *class_type* constraint `A` and `T` has a *class_type* constraint `B` then there must be an identity conversion or implicit reference conversion from `A` to `B` or an implicit reference conversion from `B` to `A`.

It is valid for `S` to have the value type constraint and `T` to have the reference type constraint. Effectively this limits `T` to the types `System.Object`, `System.ValueType`, `System.Enum`, and any interface type.

If the `where` clause for a type parameter includes a constructor constraint (which has the form `new()`), it is possible to use the `new` operator to create instances of the type ([Object creation expressions](#)). Any type argument used for a type parameter with a constructor constraint must have a public parameterless constructor (this constructor implicitly exists for any value type) or be a type parameter having the value type constraint or constructor constraint (see [Type parameter constraints](#) for details).

The following are examples of constraints:

```

interface IPrintable
{
    void Print();
}

interface IComparable<T>
{
    int CompareTo(T value);
}

interface IKeyProvider<T>
{
    T GetKey();
}

class Printer<T> where T: IPrintable {...}

class SortedList<T> where T: IComparable<T> {...}

class Dictionary<K,V>
    where K: IComparable<K>
    where V: IPrintable, IKeyProvider<K>, new()
{
    ...
}

```

The following example is in error because it causes a circularity in the dependency graph of the type parameters:

```

class Circular<S,T>
    where S: T
    where T: S           // Error, circularity in dependency graph
{
    ...
}

```

The following examples illustrate additional invalid situations:

```

class Sealed<S,T>
    where S: T
    where T: struct       // Error, T is sealed
{
    ...
}

class A {...}

class B {...}

class Incompat<S,T>
    where S: A, T
    where T: B           // Error, incompatible class-type constraints
{
    ...
}

class StructWithClass<S,T,U>
    where S: struct, T
    where T: U
    where U: A           // Error, A incompatible with struct
{
    ...
}

```

The **effective base class** of a type parameter `T` is defined as follows:

- If `T` has no primary constraints or type parameter constraints, its effective base class is `object`.
- If `T` has the value type constraint, its effective base class is `System.ValueType`.
- If `T` has a *class_type* constraint `C` but no *type_parameter* constraints, its effective base class is `C`.
- If `T` has no *class_type* constraint but has one or more *type_parameter* constraints, its effective base class is the most encompassed type ([Lifted conversion operators](#)) in the set of effective base classes of its *type_parameter* constraints. The consistency rules ensure that such a most encompassed type exists.
- If `T` has both a *class_type* constraint and one or more *type_parameter* constraints, its effective base class is the most encompassed type ([Lifted conversion operators](#)) in the set consisting of the *class_type* constraint of `T` and the effective base classes of its *type_parameter* constraints. The consistency rules ensure that such a most encompassed type exists.
- If `T` has the reference type constraint but no *class_type* constraints, its effective base class is `object`.

For the purpose of these rules, if `T` has a constraint `V` that is a *value_type*, use instead the most specific base type of `V` that is a *class_type*. This can never happen in an explicitly given constraint, but may occur when the constraints of a generic method are implicitly inherited by an overriding method declaration or an explicit implementation of an interface method.

These rules ensure that the effective base class is always a *class_type*.

The **effective interface set** of a type parameter `T` is defined as follows:

- If `T` has no *secondary_constraints*, its effective interface set is empty.
- If `T` has *interface_type* constraints but no *type_parameter* constraints, its effective interface set is its set of *interface_type* constraints.
- If `T` has no *interface_type* constraints but has *type_parameter* constraints, its effective interface set is the union of the effective interface sets of its *type_parameter* constraints.
- If `T` has both *interface_type* constraints and *type_parameter* constraints, its effective interface set is the union of its set of *interface_type* constraints and the effective interface sets of its *type_parameter* constraints.

A type parameter is **known to be a reference type** if it has the reference type constraint or its effective base class is not `object` or `System.ValueType`.

Values of a constrained type parameter type can be used to access the instance members implied by the constraints. In the example

```
interface IPrintable
{
    void Print();
}

class Printer<T> where T: IPrintable
{
    void PrintOne(T x) {
        x.Print();
    }
}
```

the methods of `IPrintable` can be invoked directly on `x` because `T` is constrained to always implement `IPrintable`.

Class body

The *class_body* of a class defines the members of that class.

```
class_body
: '{' class_member_declaration* '}'
;
```

Partial types

A type declaration can be split across multiple *partial type declarations*. The type declaration is constructed from its parts by following the rules in this section, whereupon it is treated as a single declaration during the remainder of the compile-time and run-time processing of the program.

A *class_declaration*, *struct_declaration* or *interface_declaration* represents a partial type declaration if it includes a `partial` modifier. `partial` is not a keyword, and only acts as a modifier if it appears immediately before one of the keywords `class`, `struct` or `interface` in a type declaration, or before the type `void` in a method declaration. In other contexts it can be used as a normal identifier.

Each part of a partial type declaration must include a `partial` modifier. It must have the same name and be declared in the same namespace or type declaration as the other parts. The `partial` modifier indicates that additional parts of the type declaration may exist elsewhere, but the existence of such additional parts is not a requirement; it is valid for a type with a single declaration to include the `partial` modifier.

All parts of a partial type must be compiled together such that the parts can be merged at compile-time into a single type declaration. Partial types specifically do not allow already compiled types to be extended.

Nested types may be declared in multiple parts by using the `partial` modifier. Typically, the containing type is declared using `partial` as well, and each part of the nested type is declared in a different part of the containing type.

The `partial` modifier is not permitted on delegate or enum declarations.

Attributes

The attributes of a partial type are determined by combining, in an unspecified order, the attributes of each of the parts. If an attribute is placed on multiple parts, it is equivalent to specifying the attribute multiple times on the type. For example, the two parts:

```
[Attr1, Attr2("hello")]
partial class A {}

[Attr3, Attr2("goodbye")]
partial class A {}
```

are equivalent to a declaration such as:

```
[Attr1, Attr2("hello"), Attr3, Attr2("goodbye")]
class A {}
```

Attributes on type parameters combine in a similar fashion.

Modifiers

When a partial type declaration includes an accessibility specification (the `public`, `protected`, `internal`, and `private` modifiers) it must agree with all other parts that include an accessibility specification. If no part of a partial type includes an accessibility specification, the type is given the appropriate default accessibility ([Declared accessibility](#)).

If one or more partial declarations of a nested type include a `new` modifier, no warning is reported if the nested

type hides an inherited member ([Hiding through inheritance](#)).

If one or more partial declarations of a class include an `abstract` modifier, the class is considered abstract ([Abstract classes](#)). Otherwise, the class is considered non-abstract.

If one or more partial declarations of a class include a `sealed` modifier, the class is considered sealed ([Sealed classes](#)). Otherwise, the class is considered unsealed.

Note that a class cannot be both abstract and sealed.

When the `unsafe` modifier is used on a partial type declaration, only that particular part is considered an unsafe context ([Unsafe contexts](#)).

Type parameters and constraints

If a generic type is declared in multiple parts, each part must state the type parameters. Each part must have the same number of type parameters, and the same name for each type parameter, in order.

When a partial generic type declaration includes constraints (`where` clauses), the constraints must agree with all other parts that include constraints. Specifically, each part that includes constraints must have constraints for the same set of type parameters, and for each type parameter the sets of primary, secondary, and constructor constraints must be equivalent. Two sets of constraints are equivalent if they contain the same members. If no part of a partial generic type specifies type parameter constraints, the type parameters are considered unconstrained.

The example

```
partial class Dictionary<K,V>
    where K: IComparable<K>
    where V: IKeyProvider<K>, IPersistable
{
    ...
}

partial class Dictionary<K,V>
    where V: IPersistable, IKeyProvider<K>
    where K: IComparable<K>
{
    ...
}

partial class Dictionary<K,V>
{
    ...
}
```

is correct because those parts that include constraints (the first two) effectively specify the same set of primary, secondary, and constructor constraints for the same set of type parameters, respectively.

Base class

When a partial class declaration includes a base class specification it must agree with all other parts that include a base class specification. If no part of a partial class includes a base class specification, the base class becomes `System.Object` ([Base classes](#)).

Base interfaces

The set of base interfaces for a type declared in multiple parts is the union of the base interfaces specified on each part. A particular base interface may only be named once on each part, but it is permitted for multiple parts to name the same base interface(s). There must only be one implementation of the members of any given base interface.

In the example

```
partial class C: IA, IB {...}

partial class C: IC {...}

partial class C: IA, IB {...}
```

the set of base interfaces for class `C` is `IA`, `IB`, and `IC`.

Typically, each part provides an implementation of the interface(s) declared on that part; however, this is not a requirement. A part may provide the implementation for an interface declared on a different part:

```
partial class X
{
    int IComparable.CompareTo(object o) {...}
}

partial class X: IComparable
{
    ...
}
```

Members

With the exception of partial methods ([Partial methods](#)), the set of members of a type declared in multiple parts is simply the union of the set of members declared in each part. The bodies of all parts of the type declaration share the same declaration space ([Declarations](#)), and the scope of each member ([Scopes](#)) extends to the bodies of all the parts. The accessibility domain of any member always includes all the parts of the enclosing type; a `private` member declared in one part is freely accessible from another part. It is a compile-time error to declare the same member in more than one part of the type, unless that member is a type with the `partial` modifier.

```
partial class A
{
    int x;                // Error, cannot declare x more than once

    partial class Inner    // Ok, Inner is a partial type
    {
        int y;
    }
}

partial class A
{
    int x;                // Error, cannot declare x more than once

    partial class Inner    // Ok, Inner is a partial type
    {
        int z;
    }
}
```

The ordering of members within a type is rarely significant to C# code, but may be significant when interfacing with other languages and environments. In these cases, the ordering of members within a type declared in multiple parts is undefined.

Partial methods

Partial methods can be defined in one part of a type declaration and implemented in another. The

implementation is optional; if no part implements the partial method, the partial method declaration and all calls to it are removed from the type declaration resulting from the combination of the parts.

Partial methods cannot define access modifiers, but are implicitly `private`. Their return type must be `void`, and their parameters cannot have the `out` modifier. The identifier `partial` is recognized as a special keyword in a method declaration only if it appears right before the `void` type; otherwise it can be used as a normal identifier. A partial method cannot explicitly implement interface methods.

There are two kinds of partial method declarations: If the body of the method declaration is a semicolon, the declaration is said to be a **defining partial method declaration**. If the body is given as a *block*, the declaration is said to be an **implementing partial method declaration**. Across the parts of a type declaration there can be only one defining partial method declaration with a given signature, and there can be only one implementing partial method declaration with a given signature. If an implementing partial method declaration is given, a corresponding defining partial method declaration must exist, and the declarations must match as specified in the following:

- The declarations must have the same modifiers (although not necessarily in the same order), method name, number of type parameters and number of parameters.
- Corresponding parameters in the declarations must have the same modifiers (although not necessarily in the same order) and the same types (modulo differences in type parameter names).
- Corresponding type parameters in the declarations must have the same constraints (modulo differences in type parameter names).

An implementing partial method declaration can appear in the same part as the corresponding defining partial method declaration.

Only a defining partial method participates in overload resolution. Thus, whether or not an implementing declaration is given, invocation expressions may resolve to invocations of the partial method. Because a partial method always returns `void`, such invocation expressions will always be expression statements. Furthermore, because a partial method is implicitly `private`, such statements will always occur within one of the parts of the type declaration within which the partial method is declared.

If no part of a partial type declaration contains an implementing declaration for a given partial method, any expression statement invoking it is simply removed from the combined type declaration. Thus the invocation expression, including any constituent expressions, has no effect at run-time. The partial method itself is also removed and will not be a member of the combined type declaration.

If an implementing declaration exist for a given partial method, the invocations of the partial methods are retained. The partial method gives rise to a method declaration similar to the implementing partial method declaration except for the following:

- The `partial` modifier is not included
- The attributes in the resulting method declaration are the combined attributes of the defining and the implementing partial method declaration in unspecified order. Duplicates are not removed.
- The attributes on the parameters of the resulting method declaration are the combined attributes of the corresponding parameters of the defining and the implementing partial method declaration in unspecified order. Duplicates are not removed.

If a defining declaration but not an implementing declaration is given for a partial method M, the following restrictions apply:

- It is a compile-time error to create a delegate to method ([Delegate creation expressions](#)).
- It is a compile-time error to refer to `M` inside an anonymous function that is converted to an expression tree type ([Evaluation of anonymous function conversions to expression tree types](#)).
- Expressions occurring as part of an invocation of `M` do not affect the definite assignment state ([Definite](#)

[assignment](#)), which can potentially lead to compile-time errors.

- `M` cannot be the entry point for an application ([Application Startup](#)).

Partial methods are useful for allowing one part of a type declaration to customize the behavior of another part, e.g., one that is generated by a tool. Consider the following partial class declaration:

```
partial class Customer
{
    string name;

    public string Name {
        get { return name; }
        set {
            OnNameChanging(value);
            name = value;
            OnNameChanged();
        }
    }

    partial void OnNameChanging(string newName);

    partial void OnNameChanged();
}
```

If this class is compiled without any other parts, the defining partial method declarations and their invocations will be removed, and the resulting combined class declaration will be equivalent to the following:

```
class Customer
{
    string name;

    public string Name {
        get { return name; }
        set { name = value; }
    }
}
```

Assume that another part is given, however, which provides implementing declarations of the partial methods:

```
partial class Customer
{
    partial void OnNameChanging(string newName)
    {
        Console.WriteLine("Changing " + name + " to " + newName);
    }

    partial void OnNameChanged()
    {
        Console.WriteLine("Changed to " + name);
    }
}
```

Then the resulting combined class declaration will be equivalent to the following:

```

class Customer
{
    string name;

    public string Name {
        get { return name; }
        set {
            OnNameChanging(value);
            name = value;
            OnNameChanged();
        }
    }

    void OnNameChanging(string newName)
    {
        Console.WriteLine("Changing " + name + " to " + newName);
    }

    void OnNameChanged()
    {
        Console.WriteLine("Changed to " + name);
    }
}

```

Name binding

Although each part of an extensible type must be declared within the same namespace, the parts are typically written within different namespace declarations. Thus, different `using` directives ([Using directives](#)) may be present for each part. When interpreting simple names ([Type inference](#)) within one part, only the `using` directives of the namespace declaration(s) enclosing that part are considered. This may result in the same identifier having different meanings in different parts:

```

namespace N
{
    using List = System.Collections.ArrayList;

    partial class A
    {
        List x;           // x has type System.Collections.ArrayList
    }
}

namespace N
{
    using List = Widgets.LinkedList;

    partial class A
    {
        List y;           // y has type Widgets.LinkedList
    }
}

```

Class members

The members of a class consist of the members introduced by its *class_member_declarations* and the members inherited from the direct base class.

```

class_member_declaration
: constant_declaration
| field_declaration
| method_declaration
| property_declaration
| event_declaration
| indexer_declaration
| operator_declaration
| constructor_declaration
| destructor_declaration
| static_constructor_declaration
| type_declaration
;

```

The members of a class type are divided into the following categories:

- Constants, which represent constant values associated with the class ([Constants](#)).
- Fields, which are the variables of the class ([Fields](#)).
- Methods, which implement the computations and actions that can be performed by the class ([Methods](#)).
- Properties, which define named characteristics and the actions associated with reading and writing those characteristics ([Properties](#)).
- Events, which define notifications that can be generated by the class ([Events](#)).
- Indexers, which permit instances of the class to be indexed in the same way (syntactically) as arrays ([Indexers](#)).
- Operators, which define the expression operators that can be applied to instances of the class ([Operators](#)).
- Instance constructors, which implement the actions required to initialize instances of the class ([Instance constructors](#)).
- Destructors, which implement the actions to be performed before instances of the class are permanently discarded ([Destructors](#)).
- Static constructors, which implement the actions required to initialize the class itself ([Static constructors](#)).
- Types, which represent the types that are local to the class ([Nested types](#)).

Members that can contain executable code are collectively known as the *function members* of the class type. The function members of a class type are the methods, properties, events, indexers, operators, instance constructors, destructors, and static constructors of that class type.

A *class_declaration* creates a new declaration space ([Declarations](#)), and the *class_member_declarations* immediately contained by the *class_declaration* introduce new members into this declaration space. The following rules apply to *class_member_declarations*:

- Instance constructors, destructors and static constructors must have the same name as the immediately enclosing class. All other members must have names that differ from the name of the immediately enclosing class.
- The name of a constant, field, property, event, or type must differ from the names of all other members declared in the same class.
- The name of a method must differ from the names of all other non-methods declared in the same class. In addition, the signature ([Signatures and overloading](#)) of a method must differ from the signatures of all other methods declared in the same class, and two methods declared in the same class may not have signatures that differ solely by `ref` and `out`.
- The signature of an instance constructor must differ from the signatures of all other instance constructors declared in the same class, and two constructors declared in the same class may not have signatures that differ solely by `ref` and `out`.
- The signature of an indexer must differ from the signatures of all other indexers declared in the same class.
- The signature of an operator must differ from the signatures of all other operators declared in the same

class.

The inherited members of a class type ([Inheritance](#)) are not part of the declaration space of a class. Thus, a derived class is allowed to declare a member with the same name or signature as an inherited member (which in effect hides the inherited member).

The instance type

Each class declaration has an associated bound type ([Bound and unbound types](#)), the *instance type*. For a generic class declaration, the instance type is formed by creating a constructed type ([Constructed types](#)) from the type declaration, with each of the supplied type arguments being the corresponding type parameter. Since the instance type uses the type parameters, it can only be used where the type parameters are in scope; that is, inside the class declaration. The instance type is the type of `this` for code written inside the class declaration. For non-generic classes, the instance type is simply the declared class. The following shows several class declarations along with their instance types:

```
class A<T>                // instance type: A<T>
{
    class B {}            // instance type: A<T>.B
    class C<U> {}         // instance type: A<T>.C<U>
}

class D {}                // instance type: D
```

Members of constructed types

The non-inherited members of a constructed type are obtained by substituting, for each *type_parameter* in the member declaration, the corresponding *type_argument* of the constructed type. The substitution process is based on the semantic meaning of type declarations, and is not simply textual substitution.

For example, given the generic class declaration

```
class Gen<T,U>
{
    public T[, ] a;
    public void G(int i, T t, Gen<U,T> gt) {...}
    public U Prop { get {...} set {...} }
    public int H(double d) {...}
}
```

the constructed type `Gen<int[],IComparable<string>>` has the following members:

```
public int[, ][ ] a;
public void G(int i, int[] t, Gen<IComparable<string>,int[]> gt) {...}
public IComparable<string> Prop { get {...} set {...} }
public int H(double d) {...}
```

The type of the member `a` in the generic class declaration `Gen` is "two-dimensional array of `T`", so the type of the member `a` in the constructed type above is "two-dimensional array of one-dimensional array of `int`", or `int[,][]`.

Within instance function members, the type of `this` is the instance type ([The instance type](#)) of the containing declaration.

All members of a generic class can use type parameters from any enclosing class, either directly or as part of a constructed type. When a particular closed constructed type ([Open and closed types](#)) is used at run-time, each use of a type parameter is replaced with the actual type argument supplied to the constructed type. For example:

```

class C<V>
{
    public V f1;
    public C<V> f2 = null;

    public C(V x) {
        this.f1 = x;
        this.f2 = this;
    }
}

class Application
{
    static void Main() {
        C<int> x1 = new C<int>(1);
        Console.WriteLine(x1.f1);          // Prints 1

        C<double> x2 = new C<double>(3.1415);
        Console.WriteLine(x2.f1);          // Prints 3.1415
    }
}

```

Inheritance

A class *inherits* the members of its direct base class type. Inheritance means that a class implicitly contains all members of its direct base class type, except for the instance constructors, destructors and static constructors of the base class. Some important aspects of inheritance are:

- Inheritance is transitive. If `C` is derived from `B`, and `B` is derived from `A`, then `C` inherits the members declared in `B` as well as the members declared in `A`.
- A derived class extends its direct base class. A derived class can add new members to those it inherits, but it cannot remove the definition of an inherited member.
- Instance constructors, destructors, and static constructors are not inherited, but all other members are, regardless of their declared accessibility ([Member access](#)). However, depending on their declared accessibility, inherited members might not be accessible in a derived class.
- A derived class can *hide* ([Hiding through inheritance](#)) inherited members by declaring new members with the same name or signature. Note however that hiding an inherited member does not remove that member—it merely makes that member inaccessible directly through the derived class.
- An instance of a class contains a set of all instance fields declared in the class and its base classes, and an implicit conversion ([Implicit reference conversions](#)) exists from a derived class type to any of its base class types. Thus, a reference to an instance of some derived class can be treated as a reference to an instance of any of its base classes.
- A class can declare virtual methods, properties, and indexers, and derived classes can override the implementation of these function members. This enables classes to exhibit polymorphic behavior wherein the actions performed by a function member invocation varies depending on the run-time type of the instance through which that function member is invoked.

The inherited member of a constructed class type are the members of the immediate base class type ([Base classes](#)), which is found by substituting the type arguments of the constructed type for each occurrence of the corresponding type parameters in the *class_base* specification. These members, in turn, are transformed by substituting, for each *type_parameter* in the member declaration, the corresponding *type_argument* of the *class_base* specification.

```

class B<U>
{
    public U F(long index) {...}
}

class D<T>: B<T[]>
{
    public T G(string s) {...}
}

```

In the above example, the constructed type `D<int>` has a non-inherited member `public int G(string s)` obtained by substituting the type argument `int` for the type parameter `T`. `D<int>` also has an inherited member from the class declaration `B`. This inherited member is determined by first determining the base class type `B<int[]>` of `D<int>` by substituting `int` for `T` in the base class specification `B<T[]>`. Then, as a type argument to `B`, `int[]` is substituted for `U` in `public U F(long index)`, yielding the inherited member `public int[] F(long index)`.

The new modifier

A *class_member_declaration* is permitted to declare a member with the same name or signature as an inherited member. When this occurs, the derived class member is said to **hide** the base class member. Hiding an inherited member is not considered an error, but it does cause the compiler to issue a warning. To suppress the warning, the declaration of the derived class member can include a `new` modifier to indicate that the derived member is intended to hide the base member. This topic is discussed further in [Hiding through inheritance](#).

If a `new` modifier is included in a declaration that doesn't hide an inherited member, a warning to that effect is issued. This warning is suppressed by removing the `new` modifier.

Access modifiers

A *class_member_declaration* can have any one of the five possible kinds of declared accessibility ([Declared accessibility](#)): `public`, `protected internal`, `protected`, `internal`, or `private`. Except for the `protected internal` combination, it is a compile-time error to specify more than one access modifier. When a *class_member_declaration* does not include any access modifiers, `private` is assumed.

Constituent types

Types that are used in the declaration of a member are called the constituent types of that member. Possible constituent types are the type of a constant, field, property, event, or indexer, the return type of a method or operator, and the parameter types of a method, indexer, operator, or instance constructor. The constituent types of a member must be at least as accessible as that member itself ([Accessibility constraints](#)).

Static and instance members

Members of a class are either **static members** or **instance members**. Generally speaking, it is useful to think of static members as belonging to class types and instance members as belonging to objects (instances of class types).

When a field, method, property, event, operator, or constructor declaration includes a `static` modifier, it declares a static member. In addition, a constant or type declaration implicitly declares a static member. Static members have the following characteristics:

- When a static member `M` is referenced in a *member_access* ([Member access](#)) of the form `E.M`, `E` must denote a type containing `M`. It is a compile-time error for `E` to denote an instance.
- A static field identifies exactly one storage location to be shared by all instances of a given closed class type. No matter how many instances of a given closed class type are created, there is only ever one copy of a static field.
- A static function member (method, property, event, operator, or constructor) does not operate on a specific

instance, and it is a compile-time error to refer to `this` in such a function member.

When a field, method, property, event, indexer, constructor, or destructor declaration does not include a `static` modifier, it declares an instance member. (An instance member is sometimes called a non-static member.) Instance members have the following characteristics:

- When an instance member `M` is referenced in a *member_access* (Member access) of the form `E.M`, `E` must denote an instance of a type containing `M`. It is a binding-time error for `E` to denote a type.
- Every instance of a class contains a separate set of all instance fields of the class.
- An instance function member (method, property, indexer, instance constructor, or destructor) operates on a given instance of the class, and this instance can be accessed as `this` (This access).

The following example illustrates the rules for accessing static and instance members:

```
class Test
{
    int x;
    static int y;

    void F() {
        x = 1;           // Ok, same as this.x = 1
        y = 1;           // Ok, same as Test.y = 1
    }

    static void G() {
        x = 1;           // Error, cannot access this.x
        y = 1;           // Ok, same as Test.y = 1
    }

    static void Main() {
        Test t = new Test();
        t.x = 1;         // Ok
        t.y = 1;         // Error, cannot access static member through instance
        Test.x = 1;      // Error, cannot access instance member through type
        Test.y = 1;      // Ok
    }
}
```

The `F` method shows that in an instance function member, a *simple_name* (Simple names) can be used to access both instance members and static members. The `G` method shows that in a static function member, it is a compile-time error to access an instance member through a *simple_name*. The `Main` method shows that in a *member_access* (Member access), instance members must be accessed through instances, and static members must be accessed through types.

Nested types

A type declared within a class or struct declaration is called a *nested type*. A type that is declared within a compilation unit or namespace is called a *non-nested type*.

In the example

```

using System;

class A
{
    class B
    {
        static void F() {
            Console.WriteLine("A.B.F");
        }
    }
}

```

class `B` is a nested type because it is declared within class `A`, and class `A` is a non-nested type because it is declared within a compilation unit.

Fully qualified name

The fully qualified name ([Fully qualified names](#)) for a nested type is `S.N` where `S` is the fully qualified name of the type in which type `N` is declared.

Declared accessibility

Non-nested types can have `public` or `internal` declared accessibility and have `internal` declared accessibility by default. Nested types can have these forms of declared accessibility too, plus one or more additional forms of declared accessibility, depending on whether the containing type is a class or struct:

- A nested type that is declared in a class can have any of five forms of declared accessibility (`public`, `protected internal`, `protected`, `internal`, or `private`) and, like other class members, defaults to `private` declared accessibility.
- A nested type that is declared in a struct can have any of three forms of declared accessibility (`public`, `internal`, or `private`) and, like other struct members, defaults to `private` declared accessibility.

The example

```

public class List
{
    // Private data structure
    private class Node
    {
        public object Data;
        public Node Next;

        public Node(object data, Node next) {
            this.Data = data;
            this.Next = next;
        }
    }

    private Node first = null;
    private Node last = null;

    // Public interface
    public void AddToFront(object o) {...}
    public void AddToBack(object o) {...}
    public object RemoveFromFront() {...}
    public object RemoveFromBack() {...}
    public int Count { get {...} }
}

```

declares a private nested class `Node`.

Hiding

A nested type may hide ([Name hiding](#)) a base member. The `new` modifier is permitted on nested type declarations so that hiding can be expressed explicitly. The example

```
using System;

class Base
{
    public static void M() {
        Console.WriteLine("Base.M");
    }
}

class Derived: Base
{
    new public class M
    {
        public static void F() {
            Console.WriteLine("Derived.M.F");
        }
    }
}

class Test
{
    static void Main() {
        Derived.M.F();
    }
}
```

shows a nested class `M` that hides the method `M` defined in `Base`.

this access

A nested type and its containing type do not have a special relationship with regard to *this_access* ([This access](#)). Specifically, `this` within a nested type cannot be used to refer to instance members of the containing type. In cases where a nested type needs access to the instance members of its containing type, access can be provided by providing the `this` for the instance of the containing type as a constructor argument for the nested type. The following example

```

using System;

class C
{
    int i = 123;

    public void F() {
        Nested n = new Nested(this);
        n.G();
    }

    public class Nested
    {
        C this_c;

        public Nested(C c) {
            this_c = c;
        }

        public void G() {
            Console.WriteLine(this_c.i);
        }
    }
}

class Test
{
    static void Main() {
        C c = new C();
        c.F();
    }
}

```

shows this technique. An instance of `C` creates an instance of `Nested` and passes its own `this` to `Nested`'s constructor in order to provide subsequent access to `C`'s instance members.

Access to private and protected members of the containing type

A nested type has access to all of the members that are accessible to its containing type, including members of the containing type that have `private` and `protected` declared accessibility. The example

```

using System;

class C
{
    private static void F() {
        Console.WriteLine("C.F");
    }

    public class Nested
    {
        public static void G() {
            F();
        }
    }
}

class Test
{
    static void Main() {
        C.Nested.G();
    }
}

```

shows a class `C` that contains a nested class `Nested`. Within `Nested`, the method `G` calls the static method `F` defined in `C`, and `F` has private declared accessibility.

A nested type also may access protected members defined in a base type of its containing type. In the example

```
using System;

class Base
{
    protected void F() {
        Console.WriteLine("Base.F");
    }
}

class Derived: Base
{
    public class Nested
    {
        public void G() {
            Derived d = new Derived();
            d.F();        // ok
        }
    }
}

class Test
{
    static void Main() {
        Derived.Nested n = new Derived.Nested();
        n.G();
    }
}
```

the nested class `Derived.Nested` accesses the protected method `F` defined in `Derived`'s base class, `Base`, by calling through an instance of `Derived`.

Nested types in generic classes

A generic class declaration can contain nested type declarations. The type parameters of the enclosing class can be used within the nested types. A nested type declaration can contain additional type parameters that apply only to the nested type.

Every type declaration contained within a generic class declaration is implicitly a generic type declaration. When writing a reference to a type nested within a generic type, the containing constructed type, including its type arguments, must be named. However, from within the outer class, the nested type can be used without qualification; the instance type of the outer class can be implicitly used when constructing the nested type. The following example shows three different correct ways to refer to a constructed type created from `Inner`; the first two are equivalent:

```

class Outer<T>
{
    class Inner<U>
    {
        public static void F(T t, U u) {...}
    }

    static void F(T t) {
        Outer<T>.Inner<string>.F(t, "abc");    // These two statements have
        Inner<string>.F(t, "abc");              // the same effect

        Outer<int>.Inner<string>.F(3, "abc");    // This type is different

        Outer.Inner<string>.F(t, "abc");        // Error, Outer needs type arg
    }
}

```

Although it is bad programming style, a type parameter in a nested type can hide a member or type parameter declared in the outer type:

```

class Outer<T>
{
    class Inner<T>          // Valid, hides Outer's T
    {
        public T t;        // Refers to Inner's T
    }
}

```

Reserved member names

To facilitate the underlying C# run-time implementation, for each source member declaration that is a property, event, or indexer, the implementation must reserve two method signatures based on the kind of the member declaration, its name, and its type. It is a compile-time error for a program to declare a member whose signature matches one of these reserved signatures, even if the underlying run-time implementation does not make use of these reservations.

The reserved names do not introduce declarations, thus they do not participate in member lookup. However, a declaration's associated reserved method signatures do participate in inheritance ([Inheritance](#)), and can be hidden with the `new` modifier ([The new modifier](#)).

The reservation of these names serves three purposes:

- To allow the underlying implementation to use an ordinary identifier as a method name for get or set access to the C# language feature.
- To allow other languages to interoperate using an ordinary identifier as a method name for get or set access to the C# language feature.
- To help ensure that the source accepted by one conforming compiler is accepted by another, by making the specifics of reserved member names consistent across all C# implementations.

The declaration of a destructor ([Destructors](#)) also causes a signature to be reserved ([Member names reserved for destructors](#)).

Member names reserved for properties

For a property `P` ([Properties](#)) of type `T`, the following signatures are reserved:

```

T get_P();
void set_P(T value);

```

Both signatures are reserved, even if the property is read-only or write-only.

In the example

```
using System;

class A
{
    public int P {
        get { return 123; }
    }
}

class B: A
{
    new public int get_P() {
        return 456;
    }

    new public void set_P(int value) {
    }
}

class Test
{
    static void Main() {
        B b = new B();
        A a = b;
        Console.WriteLine(a.P);
        Console.WriteLine(b.P);
        Console.WriteLine(b.get_P());
    }
}
```

a class `A` defines a read-only property `P`, thus reserving signatures for `get_P` and `set_P` methods. A class `B` derives from `A` and hides both of these reserved signatures. The example produces the output:

```
123
123
456
```

Member names reserved for events

For an event `E` ([Events](#)) of delegate type `T`, the following signatures are reserved:

```
void add_E(T handler);
void remove_E(T handler);
```

Member names reserved for indexers

For an indexer ([Indexers](#)) of type `T` with parameter-list `L`, the following signatures are reserved:

```
T get_Item(L);
void set_Item(L, T value);
```

Both signatures are reserved, even if the indexer is read-only or write-only.

Furthermore the member name `Item` is reserved.

Member names reserved for destructors

For a class containing a destructor ([Destructors](#)), the following signature is reserved:

```
void Finalize();
```

Constants

A **constant** is a class member that represents a constant value: a value that can be computed at compile-time. A *constant_declaration* introduces one or more constants of a given type.

```
constant_declaration
    : attributes? constant_modifier* 'const' type constant_declarators ';'
    ;

constant_modifier
    : 'new'
    | 'public'
    | 'protected'
    | 'internal'
    | 'private'
    ;

constant_declarators
    : constant_declarator (',' constant_declarator)*
    ;

constant_declarator
    : identifier '=' constant_expression
    ;
```

A *constant_declaration* may include a set of *attributes* ([Attributes](#)), a `new` modifier ([The new modifier](#)), and a valid combination of the four access modifiers ([Access modifiers](#)). The attributes and modifiers apply to all of the members declared by the *constant_declaration*. Even though constants are considered static members, a *constant_declaration* neither requires nor allows a `static` modifier. It is an error for the same modifier to appear multiple times in a constant declaration.

The *type* of a *constant_declaration* specifies the type of the members introduced by the declaration. The type is followed by a list of *constant_declarators*, each of which introduces a new member. A *constant_declarator* consists of an *identifier* that names the member, followed by an "=" token, followed by a *constant_expression* ([Constant expressions](#)) that gives the value of the member.

The *type* specified in a constant declaration must be `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `long`, `ulong`, `char`, `float`, `double`, `decimal`, `bool`, `string`, an *enum_type*, or a *reference_type*. Each *constant_expression* must yield a value of the target type or of a type that can be converted to the target type by an implicit conversion ([Implicit conversions](#)).

The *type* of a constant must be at least as accessible as the constant itself ([Accessibility constraints](#)).

The value of a constant is obtained in an expression using a *simple_name* ([Simple names](#)) or a *member_access* ([Member access](#)).

A constant can itself participate in a *constant_expression*. Thus, a constant may be used in any construct that requires a *constant_expression*. Examples of such constructs include `case` labels, `goto case` statements, `enum` member declarations, attributes, and other constant declarations.

As described in [Constant expressions](#), a *constant_expression* is an expression that can be fully evaluated at compile-time. Since the only way to create a non-null value of a *reference_type* other than `string` is to apply the `new` operator, and since the `new` operator is not permitted in a *constant_expression*, the only possible value for constants of *reference_types* other than `string` is `null`.

When a symbolic name for a constant value is desired, but when the type of that value is not permitted in a constant declaration, or when the value cannot be computed at compile-time by a *constant_expression*, a `readonly` field ([Readonly fields](#)) may be used instead.

A constant declaration that declares multiple constants is equivalent to multiple declarations of single constants with the same attributes, modifiers, and type. For example

```
class A
{
    public const double X = 1.0, Y = 2.0, Z = 3.0;
}
```

is equivalent to

```
class A
{
    public const double X = 1.0;
    public const double Y = 2.0;
    public const double Z = 3.0;
}
```

Constants are permitted to depend on other constants within the same program as long as the dependencies are not of a circular nature. The compiler automatically arranges to evaluate the constant declarations in the appropriate order. In the example

```
class A
{
    public const int X = B.Z + 1;
    public const int Y = 10;
}

class B
{
    public const int Z = A.Y + 1;
}
```

the compiler first evaluates `A.Y`, then evaluates `B.Z`, and finally evaluates `A.X`, producing the values `10`, `11`, and `12`. Constant declarations may depend on constants from other programs, but such dependencies are only possible in one direction. Referring to the example above, if `A` and `B` were declared in separate programs, it would be possible for `A.X` to depend on `B.Z`, but `B.Z` could then not simultaneously depend on `A.Y`.

Fields

A *field* is a member that represents a variable associated with an object or class. A *field_declaration* introduces one or more fields of a given type.

```

field_declaration
: attributes? field_modifier* type variable_declarators ';'
;

field_modifier
: 'new'
| 'public'
| 'protected'
| 'internal'
| 'private'
| 'static'
| 'readonly'
| 'volatile'
| field_modifier_unsafe
;

variable_declarators
: variable_declarator (',' variable_declarator)*
;

variable_declarator
: identifier ('=' variable_initializer)?
;

variable_initializer
: expression
| array_initializer
;

```

A *field_declaration* may include a set of *attributes* ([Attributes](#)), a `new` modifier ([The new modifier](#)), a valid combination of the four access modifiers ([Access modifiers](#)), and a `static` modifier ([Static and instance fields](#)). In addition, a *field_declaration* may include a `readonly` modifier ([Readonly fields](#)) or a `volatile` modifier ([Volatile fields](#)) but not both. The attributes and modifiers apply to all of the members declared by the *field_declaration*. It is an error for the same modifier to appear multiple times in a field declaration.

The *type* of a *field_declaration* specifies the type of the members introduced by the declaration. The type is followed by a list of *variable_declarators*, each of which introduces a new member. A *variable_declarator* consists of an *identifier* that names that member, optionally followed by an "=" token and a *variable_initializer* ([Variable initializers](#)) that gives the initial value of that member.

The *type* of a field must be at least as accessible as the field itself ([Accessibility constraints](#)).

The value of a field is obtained in an expression using a *simple_name* ([Simple names](#)) or a *member_access* ([Member access](#)). The value of a non-readonly field is modified using an *assignment* ([Assignment operators](#)). The value of a non-readonly field can be both obtained and modified using postfix increment and decrement operators ([Postfix increment and decrement operators](#)) and prefix increment and decrement operators ([Prefix increment and decrement operators](#)).

A field declaration that declares multiple fields is equivalent to multiple declarations of single fields with the same attributes, modifiers, and type. For example

```

class A
{
    public static int X = 1, Y, Z = 100;
}

```

is equivalent to

```

class A
{
    public static int X = 1;
    public static int Y;
    public static int Z = 100;
}

```

Static and instance fields

When a field declaration includes a `static` modifier, the fields introduced by the declaration are *static fields*. When no `static` modifier is present, the fields introduced by the declaration are *instance fields*. Static fields and instance fields are two of the several kinds of variables ([Variables](#)) supported by C#, and at times they are referred to as *static variables* and *instance variables*, respectively.

A static field is not part of a specific instance; instead, it is shared amongst all instances of a closed type ([Open and closed types](#)). No matter how many instances of a closed class type are created, there is only ever one copy of a static field for the associated application domain.

For example:

```

class C<V>
{
    static int count = 0;

    public C() {
        count++;
    }

    public static int Count {
        get { return count; }
    }
}

class Application
{
    static void Main() {
        C<int> x1 = new C<int>();
        Console.WriteLine(C<int>.Count);           // Prints 1

        C<double> x2 = new C<double>();
        Console.WriteLine(C<int>.Count);           // Prints 1

        C<int> x3 = new C<int>();
        Console.WriteLine(C<int>.Count);           // Prints 2
    }
}

```

An instance field belongs to an instance. Specifically, every instance of a class contains a separate set of all the instance fields of that class.

When a field is referenced in a *member access* ([Member access](#)) of the form `E.M`, if `M` is a static field, `E` must denote a type containing `M`, and if `M` is an instance field, `E` must denote an instance of a type containing `M`.

The differences between static and instance members are discussed further in [Static and instance members](#).

ReadOnly fields

When a *field declaration* includes a `readonly` modifier, the fields introduced by the declaration are *readonly fields*. Direct assignments to readonly fields can only occur as part of that declaration or in an instance constructor or static constructor in the same class. (A readonly field can be assigned to multiple times in these contexts.) Specifically, direct assignments to a `readonly` field are permitted only in the following contexts:

- In the *variable_declarator* that introduces the field (by including a *variable_initializer* in the declaration).
- For an instance field, in the instance constructors of the class that contains the field declaration; for a static field, in the static constructor of the class that contains the field declaration. These are also the only contexts in which it is valid to pass a `readonly` field as an `out` or `ref` parameter.

Attempting to assign to a `readonly` field or pass it as an `out` or `ref` parameter in any other context is a compile-time error.

Using static readonly fields for constants

A `static readonly` field is useful when a symbolic name for a constant value is desired, but when the type of the value is not permitted in a `const` declaration, or when the value cannot be computed at compile-time. In the example

```
public class Color
{
    public static readonly Color Black = new Color(0, 0, 0);
    public static readonly Color White = new Color(255, 255, 255);
    public static readonly Color Red = new Color(255, 0, 0);
    public static readonly Color Green = new Color(0, 255, 0);
    public static readonly Color Blue = new Color(0, 0, 255);

    private byte red, green, blue;

    public Color(byte r, byte g, byte b) {
        red = r;
        green = g;
        blue = b;
    }
}
```

the `Black`, `White`, `Red`, `Green`, and `Blue` members cannot be declared as `const` members because their values cannot be computed at compile-time. However, declaring them `static readonly` instead has much the same effect.

Versioning of constants and static readonly fields

Constants and readonly fields have different binary versioning semantics. When an expression references a constant, the value of the constant is obtained at compile-time, but when an expression references a readonly field, the value of the field is not obtained until run-time. Consider an application that consists of two separate programs:

```
using System;

namespace Program1
{
    public class Utils
    {
        public static readonly int X = 1;
    }
}

namespace Program2
{
    class Test
    {
        static void Main() {
            Console.WriteLine(Program1.Utils.X);
        }
    }
}
```

The `Program1` and `Program2` namespaces denote two programs that are compiled separately. Because `Program1.Utils.X` is declared as a static readonly field, the value output by the `Console.WriteLine` statement is not known at compile-time, but rather is obtained at run-time. Thus, if the value of `x` is changed and `Program1` is recompiled, the `Console.WriteLine` statement will output the new value even if `Program2` isn't recompiled. However, had `x` been a constant, the value of `x` would have been obtained at the time `Program2` was compiled, and would remain unaffected by changes in `Program1` until `Program2` is recompiled.

Volatile fields

When a *field_declaration* includes a `volatile` modifier, the fields introduced by that declaration are *volatile fields*.

For non-volatile fields, optimization techniques that reorder instructions can lead to unexpected and unpredictable results in multi-threaded programs that access fields without synchronization such as that provided by the *lock_statement* ([The lock statement](#)). These optimizations can be performed by the compiler, by the run-time system, or by hardware. For volatile fields, such reordering optimizations are restricted:

- A read of a volatile field is called a *volatile read*. A volatile read has "acquire semantics"; that is, it is guaranteed to occur prior to any references to memory that occur after it in the instruction sequence.
- A write of a volatile field is called a *volatile write*. A volatile write has "release semantics"; that is, it is guaranteed to happen after any memory references prior to the write instruction in the instruction sequence.

These restrictions ensure that all threads will observe volatile writes performed by any other thread in the order in which they were performed. A conforming implementation is not required to provide a single total ordering of volatile writes as seen from all threads of execution. The type of a volatile field must be one of the following:

- A *reference_type*.
- The type `byte`, `sbyte`, `short`, `ushort`, `int`, `uint`, `char`, `float`, `bool`, `System.IntPtr`, or `System.UIntPtr`.
- An *enum_type* having an enum base type of `byte`, `sbyte`, `short`, `ushort`, `int`, or `uint`.

The example

```

using System;
using System.Threading;

class Test
{
    public static int result;
    public static volatile bool finished;

    static void Thread2() {
        result = 143;
        finished = true;
    }

    static void Main() {
        finished = false;

        // Run Thread2() in a new thread
        new Thread(new ThreadStart(Thread2)).Start();

        // Wait for Thread2 to signal that it has a result by setting
        // finished to true.
        for (;;) {
            if (finished) {
                Console.WriteLine("result = {0}", result);
                return;
            }
        }
    }
}

```

produces the output:

```

result = 143

```

In this example, the method `Main` starts a new thread that runs the method `Thread2`. This method stores a value into a non-volatile field called `result`, then stores `true` in the volatile field `finished`. The main thread waits for the field `finished` to be set to `true`, then reads the field `result`. Since `finished` has been declared `volatile`, the main thread must read the value `143` from the field `result`. If the field `finished` had not been declared `volatile`, then it would be permissible for the store to `result` to be visible to the main thread after the store to `finished`, and hence for the main thread to read the value `0` from the field `result`. Declaring `finished` as a `volatile` field prevents any such inconsistency.

Field initialization

The initial value of a field, whether it be a static field or an instance field, is the default value ([Default values](#)) of the field's type. It is not possible to observe the value of a field before this default initialization has occurred, and a field is thus never "uninitialized". The example

```

using System;

class Test
{
    static bool b;
    int i;

    static void Main() {
        Test t = new Test();
        Console.WriteLine("b = {0}, i = {1}", b, t.i);
    }
}

```

produces the output

```
b = False, i = 0
```

because `b` and `i` are both automatically initialized to default values.

Variable initializers

Field declarations may include *variable initializers*. For static fields, variable initializers correspond to assignment statements that are executed during class initialization. For instance fields, variable initializers correspond to assignment statements that are executed when an instance of the class is created.

The example

```
using System;

class Test
{
    static double x = Math.Sqrt(2.0);
    int i = 100;
    string s = "Hello";

    static void Main() {
        Test a = new Test();
        Console.WriteLine("x = {0}, i = {1}, s = {2}", x, a.i, a.s);
    }
}
```

produces the output

```
x = 1.4142135623731, i = 100, s = Hello
```

because an assignment to `x` occurs when static field initializers execute and assignments to `i` and `s` occur when the instance field initializers execute.

The default value initialization described in [Field initialization](#) occurs for all fields, including fields that have variable initializers. Thus, when a class is initialized, all static fields in that class are first initialized to their default values, and then the static field initializers are executed in textual order. Likewise, when an instance of a class is created, all instance fields in that instance are first initialized to their default values, and then the instance field initializers are executed in textual order.

It is possible for static fields with variable initializers to be observed in their default value state. However, this is strongly discouraged as a matter of style. The example

```
using System;

class Test
{
    static int a = b + 1;
    static int b = a + 1;

    static void Main() {
        Console.WriteLine("a = {0}, b = {1}", a, b);
    }
}
```

exhibits this behavior. Despite the circular definitions of `a` and `b`, the program is valid. It results in the output

```
a = 1, b = 2
```

because the static fields `a` and `b` are initialized to `0` (the default value for `int`) before their initializers are executed. When the initializer for `a` runs, the value of `b` is zero, and so `a` is initialized to `1`. When the initializer for `b` runs, the value of `a` is already `1`, and so `b` is initialized to `2`.

Static field initialization

The static field variable initializers of a class correspond to a sequence of assignments that are executed in the textual order in which they appear in the class declaration. If a static constructor ([Static constructors](#)) exists in the class, execution of the static field initializers occurs immediately prior to executing that static constructor. Otherwise, the static field initializers are executed at an implementation-dependent time prior to the first use of a static field of that class. The example

```
using System;

class Test
{
    static void Main() {
        Console.WriteLine("{0} {1}", B.Y, A.X);
    }

    public static int F(string s) {
        Console.WriteLine(s);
        return 1;
    }
}

class A
{
    public static int X = Test.F("Init A");
}

class B
{
    public static int Y = Test.F("Init B");
}
```

might produce either the output:

```
Init A
Init B
1 1
```

or the output:

```
Init B
Init A
1 1
```

because the execution of `x`'s initializer and `y`'s initializer could occur in either order; they are only constrained to occur before the references to those fields. However, in the example:

```

using System;

class Test
{
    static void Main() {
        Console.WriteLine("{0} {1}", B.Y, A.X);
    }

    public static int F(string s) {
        Console.WriteLine(s);
        return 1;
    }
}

class A
{
    static A() {}

    public static int X = Test.F("Init A");
}

class B
{
    static B() {}

    public static int Y = Test.F("Init B");
}

```

the output must be:

```

Init B
Init A
1 1

```

because the rules for when static constructors execute (as defined in [Static constructors](#)) provide that `B`'s static constructor (and hence `B`'s static field initializers) must run before `A`'s static constructor and field initializers.

Instance field initialization

The instance field variable initializers of a class correspond to a sequence of assignments that are executed immediately upon entry to any one of the instance constructors ([Constructor initializers](#)) of that class. The variable initializers are executed in the textual order in which they appear in the class declaration. The class instance creation and initialization process is described further in [Instance constructors](#).

A variable initializer for an instance field cannot reference the instance being created. Thus, it is a compile-time error to reference `this` in a variable initializer, as it is a compile-time error for a variable initializer to reference any instance member through a *simple_name*. In the example

```

class A
{
    int x = 1;
    int y = x + 1;    // Error, reference to instance member of this
}

```

the variable initializer for `y` results in a compile-time error because it references a member of the instance being created.

Methods

A *method* is a member that implements a computation or action that can be performed by an object or class.

Methods are declared using *method_declarations*:

```
method_declaration
  : method_header method_body
  ;

method_header
  : attributes? method_modifier* 'partial'? return_type member_name type_parameter_list?
    '(' formal_parameter_list? ')' type_parameter_constraints_clause*
  ;

method_modifier
  : 'new'
  | 'public'
  | 'protected'
  | 'internal'
  | 'private'
  | 'static'
  | 'virtual'
  | 'sealed'
  | 'override'
  | 'abstract'
  | 'extern'
  | 'async'
  | method_modifier_unsafe
  ;

return_type
  : type
  | 'void'
  ;

member_name
  : identifier
  | interface_type '.' identifier
  ;

method_body
  : block
  | '=>' expression ';'
  | ';'
  ;
```

A *method_declaration* may include a set of *attributes* ([Attributes](#)) and a valid combination of the four access modifiers ([Access modifiers](#)), the `new` ([The new modifier](#)), `static` ([Static and instance methods](#)), `virtual` ([Virtual methods](#)), `override` ([Override methods](#)), `sealed` ([Sealed methods](#)), `abstract` ([Abstract methods](#)), and `extern` ([External methods](#)) modifiers.

A declaration has a valid combination of modifiers if all of the following are true:

- The declaration includes a valid combination of access modifiers ([Access modifiers](#)).
- The declaration does not include the same modifier multiple times.
- The declaration includes at most one of the following modifiers: `static`, `virtual`, and `override`.
- The declaration includes at most one of the following modifiers: `new` and `override`.
- If the declaration includes the `abstract` modifier, then the declaration does not include any of the following modifiers: `static`, `virtual`, `sealed` or `extern`.
- If the declaration includes the `private` modifier, then the declaration does not include any of the following modifiers: `virtual`, `override`, or `abstract`.
- If the declaration includes the `sealed` modifier, then the declaration also includes the `override` modifier.
- If the declaration includes the `partial` modifier, then it does not include any of the following modifiers: `new`,

`public`, `protected`, `internal`, `private`, `virtual`, `sealed`, `override`, `abstract`, Or `extern`.

A method that has the `async` modifier is an async function and follows the rules described in [Async functions](#).

The *return_type* of a method declaration specifies the type of the value computed and returned by the method. The *return_type* is `void` if the method does not return a value. If the declaration includes the `partial` modifier, then the return type must be `void`.

The *member_name* specifies the name of the method. Unless the method is an explicit interface member implementation ([Explicit interface member implementations](#)), the *member_name* is simply an *identifier*. For an explicit interface member implementation, the *member_name* consists of an *interface_type* followed by a `"."` and an *identifier*.

The optional *type_parameter_list* specifies the type parameters of the method ([Type parameters](#)). If a *type_parameter_list* is specified the method is a **generic method**. If the method has an `extern` modifier, a *type_parameter_list* cannot be specified.

The optional *formal_parameter_list* specifies the parameters of the method ([Method parameters](#)).

The optional *type_parameter_constraints_clauses* specify constraints on individual type parameters ([Type parameter constraints](#)) and may only be specified if a *type_parameter_list* is also supplied, and the method does not have an `override` modifier.

The *return_type* and each of the types referenced in the *formal_parameter_list* of a method must be at least as accessible as the method itself ([Accessibility constraints](#)).

The *method_body* is either a semicolon, a **statement body** or an **expression body**. A statement body consists of a *block*, which specifies the statements to execute when the method is invoked. An expression body consists of `=>` followed by an *expression* and a semicolon, and denotes a single expression to perform when the method is invoked.

For `abstract` and `extern` methods, the *method_body* consists simply of a semicolon. For `partial` methods the *method_body* may consist of either a semicolon, a block body or an expression body. For all other methods, the *method_body* is either a block body or an expression body.

If the *method_body* consists of a semicolon, then the declaration may not include the `async` modifier.

The name, the type parameter list and the formal parameter list of a method define the signature ([Signatures and overloading](#)) of the method. Specifically, the signature of a method consists of its name, the number of type parameters and the number, modifiers, and types of its formal parameters. For these purposes, any type parameter of the method that occurs in the type of a formal parameter is identified not by its name, but by its ordinal position in the type argument list of the method. The return type is not part of a method's signature, nor are the names of the type parameters or the formal parameters.

The name of a method must differ from the names of all other non-methods declared in the same class. In addition, the signature of a method must differ from the signatures of all other methods declared in the same class, and two methods declared in the same class may not have signatures that differ solely by `ref` and `out`.

The method's *type_parameters* are in scope throughout the *method_declaration*, and can be used to form types throughout that scope in *return_type*, *method_body*, and *type_parameter_constraints_clauses* but not in *attributes*.

All formal parameters and type parameters must have different names.

Method parameters

The parameters of a method, if any, are declared by the method's *formal_parameter_list*.

```

formal_parameter_list
    : fixed_parameters
    | fixed_parameters ',' parameter_array
    | parameter_array
    ;

fixed_parameters
    : fixed_parameter (',' fixed_parameter)*
    ;

fixed_parameter
    : attributes? parameter_modifier? type identifier default_argument?
    ;

default_argument
    : '=' expression
    ;

parameter_modifier
    : 'ref'
    | 'out'
    | 'this'
    ;

parameter_array
    : attributes? 'params' array_type identifier
    ;

```

The formal parameter list consists of one or more comma-separated parameters of which only the last may be a *parameter_array*.

A *fixed_parameter* consists of an optional set of *attributes* ([Attributes](#)), an optional `ref`, `out` or `this` modifier, a *type*, an *identifier* and an optional *default_argument*. Each *fixed_parameter* declares a parameter of the given type with the given name. The `this` modifier designates the method as an extension method and is only allowed on the first parameter of a static method. Extension methods are further described in [Extension methods](#).

A *fixed_parameter* with a *default_argument* is known as an **optional parameter**, whereas a *fixed_parameter* without a *default_argument* is a **required parameter**. A required parameter may not appear after an optional parameter in a *formal_parameter_list*.

A `ref` or `out` parameter cannot have a *default_argument*. The *expression* in a *default_argument* must be one of the following:

- a *constant_expression*
- an expression of the form `new S()` where `S` is a value type
- an expression of the form `default(S)` where `S` is a value type

The *expression* must be implicitly convertible by an identity or nullable conversion to the type of the parameter.

If optional parameters occur in an implementing partial method declaration ([Partial methods](#)), an explicit interface member implementation ([Explicit interface member implementations](#)) or in a single-parameter indexer declaration ([Indexers](#)) the compiler should give a warning, since these members can never be invoked in a way that permits arguments to be omitted.

A *parameter_array* consists of an optional set of *attributes* ([Attributes](#)), a `params` modifier, an *array_type*, and an *identifier*. A parameter array declares a single parameter of the given array type with the given name. The *array_type* of a parameter array must be a single-dimensional array type ([Array types](#)). In a method invocation, a parameter array permits either a single argument of the given array type to be specified, or it permits zero or more arguments of the array element type to be specified. Parameter arrays are described further in [Parameter](#)

arrays.

A *parameter_array* may occur after an optional parameter, but cannot have a default value -- the omission of arguments for a *parameter_array* would instead result in the creation of an empty array.

The following example illustrates different kinds of parameters:

```
public void M(  
    ref int    i,  
    decimal    d,  
    bool       b = false,  
    bool?      n = false,  
    string     s = "Hello",  
    object     o = null,  
    T          t = default(T),  
    params int[] a  
) { }
```

In the *formal_parameter_list* for `M`, `i` is a required ref parameter, `d` is a required value parameter, `b`, `s`, `o` and `t` are optional value parameters and `a` is a parameter array.

A method declaration creates a separate declaration space for parameters, type parameters and local variables. Names are introduced into this declaration space by the type parameter list and the formal parameter list of the method and by local variable declarations in the *block* of the method. It is an error for two members of a method declaration space to have the same name. It is an error for the method declaration space and the local variable declaration space of a nested declaration space to contain elements with the same name.

A method invocation ([Method invocations](#)) creates a copy, specific to that invocation, of the formal parameters and local variables of the method, and the argument list of the invocation assigns values or variable references to the newly created formal parameters. Within the *block* of a method, formal parameters can be referenced by their identifiers in *simple_name* expressions ([Simple names](#)).

There are four kinds of formal parameters:

- Value parameters, which are declared without any modifiers.
- Reference parameters, which are declared with the `ref` modifier.
- Output parameters, which are declared with the `out` modifier.
- Parameter arrays, which are declared with the `params` modifier.

As described in [Signatures and overloading](#), the `ref` and `out` modifiers are part of a method's signature, but the `params` modifier is not.

Value parameters

A parameter declared with no modifiers is a value parameter. A value parameter corresponds to a local variable that gets its initial value from the corresponding argument supplied in the method invocation.

When a formal parameter is a value parameter, the corresponding argument in a method invocation must be an expression that is implicitly convertible ([Implicit conversions](#)) to the formal parameter type.

A method is permitted to assign new values to a value parameter. Such assignments only affect the local storage location represented by the value parameter—they have no effect on the actual argument given in the method invocation.

Reference parameters

A parameter declared with a `ref` modifier is a reference parameter. Unlike a value parameter, a reference parameter does not create a new storage location. Instead, a reference parameter represents the same storage location as the variable given as the argument in the method invocation.

When a formal parameter is a reference parameter, the corresponding argument in a method invocation must consist of the keyword `ref` followed by a *variable_reference* ([Precise rules for determining definite assignment](#)) of the same type as the formal parameter. A variable must be definitely assigned before it can be passed as a reference parameter.

Within a method, a reference parameter is always considered definitely assigned.

A method declared as an iterator ([Iterators](#)) cannot have reference parameters.

The example

```
using System;

class Test
{
    static void Swap(ref int x, ref int y) {
        int temp = x;
        x = y;
        y = temp;
    }

    static void Main() {
        int i = 1, j = 2;
        Swap(ref i, ref j);
        Console.WriteLine("i = {0}, j = {1}", i, j);
    }
}
```

produces the output

```
i = 2, j = 1
```

For the invocation of `Swap` in `Main`, `x` represents `i` and `y` represents `j`. Thus, the invocation has the effect of swapping the values of `i` and `j`.

In a method that takes reference parameters it is possible for multiple names to represent the same storage location. In the example

```
class A
{
    string s;

    void F(ref string a, ref string b) {
        s = "One";
        a = "Two";
        b = "Three";
    }

    void G() {
        F(ref s, ref s);
    }
}
```

the invocation of `F` in `G` passes a reference to `s` for both `a` and `b`. Thus, for that invocation, the names `s`, `a`, and `b` all refer to the same storage location, and the three assignments all modify the instance field `s`.

Output parameters

A parameter declared with an `out` modifier is an output parameter. Similar to a reference parameter, an output parameter does not create a new storage location. Instead, an output parameter represents the same storage location as the variable given as the argument in the method invocation.

When a formal parameter is an output parameter, the corresponding argument in a method invocation must consist of the keyword `out` followed by a *variable_reference* ([Precise rules for determining definite assignment](#)) of the same type as the formal parameter. A variable need not be definitely assigned before it can be passed as an output parameter, but following an invocation where a variable was passed as an output parameter, the variable is considered definitely assigned.

Within a method, just like a local variable, an output parameter is initially considered unassigned and must be definitely assigned before its value is used.

Every output parameter of a method must be definitely assigned before the method returns.

A method declared as a partial method ([Partial methods](#)) or an iterator ([Iterators](#)) cannot have output parameters.

Output parameters are typically used in methods that produce multiple return values. For example:

```
using System;

class Test
{
    static void SplitPath(string path, out string dir, out string name) {
        int i = path.Length;
        while (i > 0) {
            char ch = path[i - 1];
            if (ch == '\\' || ch == '/' || ch == ':') break;
            i--;
        }
        dir = path.Substring(0, i);
        name = path.Substring(i);
    }

    static void Main() {
        string dir, name;
        SplitPath("c:\\Windows\\System\\hello.txt", out dir, out name);
        Console.WriteLine(dir);
        Console.WriteLine(name);
    }
}
```

The example produces the output:

```
c:\Windows\System\
hello.txt
```

Note that the `dir` and `name` variables can be unassigned before they are passed to `SplitPath`, and that they are considered definitely assigned following the call.

Parameter arrays

A parameter declared with a `params` modifier is a parameter array. If a formal parameter list includes a parameter array, it must be the last parameter in the list and it must be of a single-dimensional array type. For example, the types `string[]` and `string[][]` can be used as the type of a parameter array, but the type `string[,]` can not. It is not possible to combine the `params` modifier with the modifiers `ref` and `out`.

A parameter array permits arguments to be specified in one of two ways in a method invocation:

- The argument given for a parameter array can be a single expression that is implicitly convertible ([Implicit conversions](#)) to the parameter array type. In this case, the parameter array acts precisely like a value parameter.
- Alternatively, the invocation can specify zero or more arguments for the parameter array, where each

argument is an expression that is implicitly convertible ([Implicit conversions](#)) to the element type of the parameter array. In this case, the invocation creates an instance of the parameter array type with a length corresponding to the number of arguments, initializes the elements of the array instance with the given argument values, and uses the newly created array instance as the actual argument.

Except for allowing a variable number of arguments in an invocation, a parameter array is precisely equivalent to a value parameter ([Value parameters](#)) of the same type.

The example

```
using System;

class Test
{
    static void F(params int[] args) {
        Console.WriteLine("Array contains {0} elements:", args.Length);
        foreach (int i in args)
            Console.WriteLine(" {0}", i);
        Console.WriteLine();
    }

    static void Main() {
        int[] arr = {1, 2, 3};
        F(arr);
        F(10, 20, 30, 40);
        F();
    }
}
```

produces the output

```
Array contains 3 elements: 1 2 3
Array contains 4 elements: 10 20 30 40
Array contains 0 elements:
```

The first invocation of `F` simply passes the array `a` as a value parameter. The second invocation of `F` automatically creates a four-element `int[]` with the given element values and passes that array instance as a value parameter. Likewise, the third invocation of `F` creates a zero-element `int[]` and passes that instance as a value parameter. The second and third invocations are precisely equivalent to writing:

```
F(new int[] {10, 20, 30, 40});
F(new int[] {});
```

When performing overload resolution, a method with a parameter array may be applicable either in its normal form or in its expanded form ([Applicable function member](#)). The expanded form of a method is available only if the normal form of the method is not applicable and only if an applicable method with the same signature as the expanded form is not already declared in the same type.

The example

```

using System;

class Test
{
    static void F(params object[] a) {
        Console.WriteLine("F(object[])");
    }

    static void F() {
        Console.WriteLine("F()");
    }

    static void F(object a0, object a1) {
        Console.WriteLine("F(object,object)");
    }

    static void Main() {
        F();
        F(1);
        F(1, 2);
        F(1, 2, 3);
        F(1, 2, 3, 4);
    }
}

```

produces the output

```

F();
F(object[]);
F(object,object);
F(object[]);
F(object[]);

```

In the example, two of the possible expanded forms of the method with a parameter array are already included in the class as regular methods. These expanded forms are therefore not considered when performing overload resolution, and the first and third method invocations thus select the regular methods. When a class declares a method with a parameter array, it is not uncommon to also include some of the expanded forms as regular methods. By doing so it is possible to avoid the allocation of an array instance that occurs when an expanded form of a method with a parameter array is invoked.

When the type of a parameter array is `object[]`, a potential ambiguity arises between the normal form of the method and the expanded form for a single `object` parameter. The reason for the ambiguity is that an `object[]` is itself implicitly convertible to type `object`. The ambiguity presents no problem, however, since it can be resolved by inserting a cast if needed.

The example

```

using System;

class Test
{
    static void F(params object[] args) {
        foreach (object o in args) {
            Console.Write(o.GetType().FullName);
            Console.Write(" ");
        }
        Console.WriteLine();
    }

    static void Main() {
        object[] a = {1, "Hello", 123.456};
        object o = a;
        F(a);
        F((object)a);
        F(o);
        F((object[])o);
    }
}

```

produces the output

```

System.Int32 System.String System.Double
System.Object[]
System.Object[]
System.Int32 System.String System.Double

```

In the first and last invocations of `F`, the normal form of `F` is applicable because an implicit conversion exists from the argument type to the parameter type (both are of type `object[]`). Thus, overload resolution selects the normal form of `F`, and the argument is passed as a regular value parameter. In the second and third invocations, the normal form of `F` is not applicable because no implicit conversion exists from the argument type to the parameter type (type `object` cannot be implicitly converted to type `object[]`). However, the expanded form of `F` is applicable, so it is selected by overload resolution. As a result, a one-element `object[]` is created by the invocation, and the single element of the array is initialized with the given argument value (which itself is a reference to an `object[]`).

Static and instance methods

When a method declaration includes a `static` modifier, that method is said to be a static method. When no `static` modifier is present, the method is said to be an instance method.

A static method does not operate on a specific instance, and it is a compile-time error to refer to `this` in a static method.

An instance method operates on a given instance of a class, and that instance can be accessed as `this` ([This access](#)).

When a method is referenced in a *member_access* ([Member access](#)) of the form `E.M`, if `M` is a static method, `E` must denote a type containing `M`, and if `M` is an instance method, `E` must denote an instance of a type containing `M`.

The differences between static and instance members are discussed further in [Static and instance members](#).

Virtual methods

When an instance method declaration includes a `virtual` modifier, that method is said to be a virtual method. When no `virtual` modifier is present, the method is said to be a non-virtual method.

The implementation of a non-virtual method is invariant: The implementation is the same whether the method is invoked on an instance of the class in which it is declared or an instance of a derived class. In contrast, the implementation of a virtual method can be superseded by derived classes. The process of superseding the implementation of an inherited virtual method is known as *overriding* that method ([Override methods](#)).

In a virtual method invocation, the *run-time type* of the instance for which that invocation takes place determines the actual method implementation to invoke. In a non-virtual method invocation, the *compile-time type* of the instance is the determining factor. In precise terms, when a method named `M` is invoked with an argument list `A` on an instance with a compile-time type `C` and a run-time type `R` (where `R` is either `C` or a class derived from `C`), the invocation is processed as follows:

- First, overload resolution is applied to `C`, `M`, and `A`, to select a specific method `M` from the set of methods declared in and inherited by `C`. This is described in [Method invocations](#).
- Then, if `M` is a non-virtual method, `M` is invoked.
- Otherwise, `M` is a virtual method, and the most derived implementation of `M` with respect to `R` is invoked.

For every virtual method declared in or inherited by a class, there exists a *most derived implementation* of the method with respect to that class. The most derived implementation of a virtual method `M` with respect to a class `R` is determined as follows:

- If `R` contains the introducing `virtual` declaration of `M`, then this is the most derived implementation of `M`.
- Otherwise, if `R` contains an `override` of `M`, then this is the most derived implementation of `M`.
- Otherwise, the most derived implementation of `M` with respect to `R` is the same as the most derived implementation of `M` with respect to the direct base class of `R`.

The following example illustrates the differences between virtual and non-virtual methods:

```
using System;

class A
{
    public void F() { Console.WriteLine("A.F"); }

    public virtual void G() { Console.WriteLine("A.G"); }
}

class B : A
{
    new public void F() { Console.WriteLine("B.F"); }

    public override void G() { Console.WriteLine("B.G"); }
}

class Test
{
    static void Main() {
        B b = new B();
        A a = b;
        a.F();
        b.F();
        a.G();
        b.G();
    }
}
```

In the example, `A` introduces a non-virtual method `F` and a virtual method `G`. The class `B` introduces a new non-virtual method `F`, thus hiding the inherited `F`, and also overrides the inherited method `G`. The example produces the output:

A.F
B.F
B.G
B.G

Notice that the statement `a.G()` invokes `B.G`, not `A.G`. This is because the run-time type of the instance (which is `B`), not the compile-time type of the instance (which is `A`), determines the actual method implementation to invoke.

Because methods are allowed to hide inherited methods, it is possible for a class to contain several virtual methods with the same signature. This does not present an ambiguity problem, since all but the most derived method are hidden. In the example

```
using System;

class A
{
    public virtual void F() { Console.WriteLine("A.F"); }
}

class B: A
{
    public override void F() { Console.WriteLine("B.F"); }
}

class C: B
{
    new public virtual void F() { Console.WriteLine("C.F"); }
}

class D: C
{
    public override void F() { Console.WriteLine("D.F"); }
}

class Test
{
    static void Main() {
        D d = new D();
        A a = d;
        B b = d;
        C c = d;
        a.F();
        b.F();
        c.F();
        d.F();
    }
}
```

the `C` and `D` classes contain two virtual methods with the same signature: The one introduced by `A` and the one introduced by `C`. The method introduced by `C` hides the method inherited from `A`. Thus, the override declaration in `D` overrides the method introduced by `C`, and it is not possible for `D` to override the method introduced by `A`. The example produces the output:

B.F
B.F
D.F
D.F

Note that it is possible to invoke the hidden virtual method by accessing an instance of `D` through a less

derived type in which the method is not hidden.

Override methods

When an instance method declaration includes an `override` modifier, the method is said to be an **override method**. An override method overrides an inherited virtual method with the same signature. Whereas a virtual method declaration introduces a new method, an override method declaration specializes an existing inherited virtual method by providing a new implementation of that method.

The method overridden by an `override` declaration is known as the **overridden base method**. For an override method `M` declared in a class `C`, the overridden base method is determined by examining each base class type of `C`, starting with the direct base class type of `C` and continuing with each successive direct base class type, until in a given base class type at least one accessible method is located which has the same signature as `M` after substitution of type arguments. For the purposes of locating the overridden base method, a method is considered accessible if it is `public`, if it is `protected`, if it is `protected internal`, or if it is `internal` and declared in the same program as `C`.

A compile-time error occurs unless all of the following are true for an override declaration:

- An overridden base method can be located as described above.
- There is exactly one such overridden base method. This restriction has effect only if the base class type is a constructed type where the substitution of type arguments makes the signature of two methods the same.
- The overridden base method is a virtual, abstract, or override method. In other words, the overridden base method cannot be static or non-virtual.
- The overridden base method is not a sealed method.
- The override method and the overridden base method have the same return type.
- The override declaration and the overridden base method have the same declared accessibility. In other words, an override declaration cannot change the accessibility of the virtual method. However, if the overridden base method is `protected internal` and it is declared in a different assembly than the assembly containing the override method then the override method's declared accessibility must be `protected`.
- The override declaration does not specify type-parameter-constraints-clauses. Instead the constraints are inherited from the overridden base method. Note that constraints that are type parameters in the overridden method may be replaced by type arguments in the inherited constraint. This can lead to constraints that are not legal when explicitly specified, such as value types or sealed types.

The following example demonstrates how the overriding rules work for generic classes:

```
abstract class C<T>
{
    public virtual T F() {...}
    public virtual C<T> G() {...}
    public virtual void H(C<T> x) {...}
}

class D: C<string>
{
    public override string F() {...}           // Ok
    public override C<string> G() {...}        // Ok
    public override void H(C<T> x) {...}       // Error, should be C<string>
}

class E<T,U>: C<U>
{
    public override U F() {...}               // Ok
    public override C<U> G() {...}            // Ok
    public override void H(C<T> x) {...}       // Error, should be C<U>
}
```

An override declaration can access the overridden base method using a *base_access* (Base access). In the example

```
class A
{
    int x;

    public virtual void PrintFields() {
        Console.WriteLine("x = {0}", x);
    }
}

class B: A
{
    int y;

    public override void PrintFields() {
        base.PrintFields();
        Console.WriteLine("y = {0}", y);
    }
}
```

the `base.PrintFields()` invocation in `B` invokes the `PrintFields` method declared in `A`. A *base_access* disables the virtual invocation mechanism and simply treats the base method as a non-virtual method. Had the invocation in `B` been written `((A)this).PrintFields()`, it would recursively invoke the `PrintFields` method declared in `B`, not the one declared in `A`, since `PrintFields` is virtual and the run-time type of `((A)this)` is `B`.

Only by including an `override` modifier can a method override another method. In all other cases, a method with the same signature as an inherited method simply hides the inherited method. In the example

```
class A
{
    public virtual void F() {}
}

class B: A
{
    public virtual void F() {}    // Warning, hiding inherited F()
}
```

the `F` method in `B` does not include an `override` modifier and therefore does not override the `F` method in `A`. Rather, the `F` method in `B` hides the method in `A`, and a warning is reported because the declaration does not include a `new` modifier.

In the example

```

class A
{
    public virtual void F() {}
}

class B: A
{
    new private void F() {}      // Hides A.F within body of B
}

class C: B
{
    public override void F() {}  // Ok, overrides A.F
}

```

the `F` method in `B` hides the virtual `F` method inherited from `A`. Since the new `F` in `B` has private access, its scope only includes the class body of `B` and does not extend to `C`. Therefore, the declaration of `F` in `C` is permitted to override the `F` inherited from `A`.

Sealed methods

When an instance method declaration includes a `sealed` modifier, that method is said to be a *sealed method*. If an instance method declaration includes the `sealed` modifier, it must also include the `override` modifier. Use of the `sealed` modifier prevents a derived class from further overriding the method.

In the example

```

using System;

class A
{
    public virtual void F() {
        Console.WriteLine("A.F");
    }

    public virtual void G() {
        Console.WriteLine("A.G");
    }
}

class B: A
{
    sealed override public void F() {
        Console.WriteLine("B.F");
    }

    override public void G() {
        Console.WriteLine("B.G");
    }
}

class C: B
{
    override public void G() {
        Console.WriteLine("C.G");
    }
}

```

the class `B` provides two override methods: an `F` method that has the `sealed` modifier and a `G` method that does not. `B`'s use of the `sealed` modifier prevents `C` from further overriding `F`.

Abstract methods

When an instance method declaration includes an `abstract` modifier, that method is said to be an ***abstract method***. Although an abstract method is implicitly also a virtual method, it cannot have the modifier `virtual`.

An abstract method declaration introduces a new virtual method but does not provide an implementation of that method. Instead, non-abstract derived classes are required to provide their own implementation by overriding that method. Because an abstract method provides no actual implementation, the *method_body* of an abstract method simply consists of a semicolon.

Abstract method declarations are only permitted in abstract classes ([Abstract classes](#)).

In the example

```
public abstract class Shape
{
    public abstract void Paint(Graphics g, Rectangle r);
}

public class Ellipse: Shape
{
    public override void Paint(Graphics g, Rectangle r) {
        g.DrawEllipse(r);
    }
}

public class Box: Shape
{
    public override void Paint(Graphics g, Rectangle r) {
        g.DrawRect(r);
    }
}
```

the `Shape` class defines the abstract notion of a geometrical shape object that can paint itself. The `Paint` method is abstract because there is no meaningful default implementation. The `Ellipse` and `Box` classes are concrete `Shape` implementations. Because these classes are non-abstract, they are required to override the `Paint` method and provide an actual implementation.

It is a compile-time error for a *base_access* ([Base access](#)) to reference an abstract method. In the example

```
abstract class A
{
    public abstract void F();
}

class B: A
{
    public override void F() {
        base.F(); // Error, base.F is abstract
    }
}
```

a compile-time error is reported for the `base.F()` invocation because it references an abstract method.

An abstract method declaration is permitted to override a virtual method. This allows an abstract class to force re-implementation of the method in derived classes, and makes the original implementation of the method unavailable. In the example

```

using System;

class A
{
    public virtual void F() {
        Console.WriteLine("A.F");
    }
}

abstract class B: A
{
    public abstract override void F();
}

class C: B
{
    public override void F() {
        Console.WriteLine("C.F");
    }
}

```

class `A` declares a virtual method, class `B` overrides this method with an abstract method, and class `C` overrides the abstract method to provide its own implementation.

External methods

When a method declaration includes an `extern` modifier, that method is said to be an *external method*. External methods are implemented externally, typically using a language other than C#. Because an external method declaration provides no actual implementation, the *method body* of an external method simply consists of a semicolon. An external method may not be generic.

The `extern` modifier is typically used in conjunction with a `DllImport` attribute ([Interoperation with COM and Win32 components](#)), allowing external methods to be implemented by DLLs (Dynamic Link Libraries). The execution environment may support other mechanisms whereby implementations of external methods can be provided.

When an external method includes a `DllImport` attribute, the method declaration must also include a `static` modifier. This example demonstrates the use of the `extern` modifier and the `DllImport` attribute:

```

using System.Text;
using System.Security.Permissions;
using System.Runtime.InteropServices;

class Path
{
    [DllImport("kernel32", SetLastError=true)]
    static extern bool CreateDirectory(string name, SecurityAttribute sa);

    [DllImport("kernel32", SetLastError=true)]
    static extern bool RemoveDirectory(string name);

    [DllImport("kernel32", SetLastError=true)]
    static extern int GetCurrentDirectory(int bufSize, StringBuilder buf);

    [DllImport("kernel32", SetLastError=true)]
    static extern bool SetCurrentDirectory(string name);
}

```

Partial methods (recap)

When a method declaration includes a `partial` modifier, that method is said to be a *partial method*. Partial methods can only be declared as members of partial types ([Partial types](#)), and are subject to a number of

restrictions. Partial methods are further described in [Partial methods](#).

Extension methods

When the first parameter of a method includes the `this` modifier, that method is said to be an *extension method*. Extension methods can only be declared in non-generic, non-nested static classes. The first parameter of an extension method can have no modifiers other than `this`, and the parameter type cannot be a pointer type.

The following is an example of a static class that declares two extension methods:

```
public static class Extensions
{
    public static int ToInt32(this string s) {
        return Int32.Parse(s);
    }

    public static T[] Slice<T>(this T[] source, int index, int count) {
        if (index < 0 || count < 0 || source.Length - index < count)
            throw new ArgumentException();
        T[] result = new T[count];
        Array.Copy(source, index, result, 0, count);
        return result;
    }
}
```

An extension method is a regular static method. In addition, where its enclosing static class is in scope, an extension method can be invoked using instance method invocation syntax ([Extension method invocations](#)), using the receiver expression as the first argument.

The following program uses the extension methods declared above:

```
static class Program
{
    static void Main() {
        string[] strings = { "1", "22", "333", "4444" };
        foreach (string s in strings.Slice(1, 2)) {
            Console.WriteLine(s.ToInt32());
        }
    }
}
```

The `slice` method is available on the `string[]`, and the `ToInt32` method is available on `string`, because they have been declared as extension methods. The meaning of the program is the same as the following, using ordinary static method calls:

```
static class Program
{
    static void Main() {
        string[] strings = { "1", "22", "333", "4444" };
        foreach (string s in Extensions.Slice(strings, 1, 2)) {
            Console.WriteLine(Extensions.ToInt32(s));
        }
    }
}
```

Method body

The *method body* of a method declaration consists of either a block body, an expression body or a semicolon.

The *result type* of a method is `void` if the return type is `void`, or if the method is `async` and the return type is

`System.Threading.Tasks.Task`. Otherwise, the result type of a non-async method is its return type, and the result type of an async method with return type `System.Threading.Tasks.Task<T>` is `T`.

When a method has a `void` result type and a block body, `return` statements ([The return statement](#)) in the block are not permitted to specify an expression. If execution of the block of a void method completes normally (that is, control flows off the end of the method body), that method simply returns to its current caller.

When a method has a `void` result and an expression body, the expression `E` must be a *statement_expression*, and the body is exactly equivalent to a block body of the form `{ E; }`.

When a method has a non-void result type and a block body, each `return` statement in the block must specify an expression that is implicitly convertible to the result type. The endpoint of a block body of a value-returning method must not be reachable. In other words, in a value-returning method with a block body, control is not permitted to flow off the end of the method body.

When a method has a non-void result type and an expression body, the expression must be implicitly convertible to the result type, and the body is exactly equivalent to a block body of the form `{ return E; }`.

In the example

```
class A
{
    public int F() {}           // Error, return value required

    public int G() {
        return 1;
    }

    public int H(bool b) {
        if (b) {
            return 1;
        }
        else {
            return 0;
        }
    }

    public int I(bool b) => b ? 1 : 0;
}
```

the value-returning `F` method results in a compile-time error because control can flow off the end of the method body. The `G` and `H` methods are correct because all possible execution paths end in a return statement that specifies a return value. The `I` method is correct, because its body is equivalent to a statement block with just a single return statement in it.

Method overloading

The method overload resolution rules are described in [Type inference](#).

Properties

A *property* is a member that provides access to a characteristic of an object or a class. Examples of properties include the length of a string, the size of a font, the caption of a window, the name of a customer, and so on. Properties are a natural extension of fields—both are named members with associated types, and the syntax for accessing fields and properties is the same. However, unlike fields, properties do not denote storage locations. Instead, properties have *accessors* that specify the statements to be executed when their values are read or written. Properties thus provide a mechanism for associating actions with the reading and writing of an object's attributes; furthermore, they permit such attributes to be computed.

Properties are declared using *property_declarations*:

```

property_declaration
    : attributes? property_modifier* type member_name property_body
    ;

property_modifier
    : 'new'
    | 'public'
    | 'protected'
    | 'internal'
    | 'private'
    | 'static'
    | 'virtual'
    | 'sealed'
    | 'override'
    | 'abstract'
    | 'extern'
    | property_modifier_unsafe
    ;

property_body
    : '{' accessor_declarations '}' property_initializer?
    | '=>' expression ';'
    ;

property_initializer
    : '=' variable_initializer ';'
    ;

```

A *property_declaration* may include a set of *attributes* ([Attributes](#)) and a valid combination of the four access modifiers ([Access modifiers](#)), the `new` ([The new modifier](#)), `static` ([Static and instance methods](#)), `virtual` ([Virtual methods](#)), `override` ([Override methods](#)), `sealed` ([Sealed methods](#)), `abstract` ([Abstract methods](#)), and `extern` ([External methods](#)) modifiers.

Property declarations are subject to the same rules as method declarations ([Methods](#)) with regard to valid combinations of modifiers.

The *type* of a property declaration specifies the type of the property introduced by the declaration, and the *member_name* specifies the name of the property. Unless the property is an explicit interface member implementation, the *member_name* is simply an *identifier*. For an explicit interface member implementation ([Explicit interface member implementations](#)), the *member_name* consists of an *interface_type* followed by a `"."` and an *identifier*.

The *type* of a property must be at least as accessible as the property itself ([Accessibility constraints](#)).

A *property_body* may either consist of an *accessor body* or an *expression body*. In an accessor body, *accessor_declarations*, which must be enclosed in `"{"` and `"}"` tokens, declare the accessors ([Accessors](#)) of the property. The accessors specify the executable statements associated with reading and writing the property.

An expression body consisting of `=>` followed by an *expression* `E` and a semicolon is exactly equivalent to the statement body `{ get { return E; } }`, and can therefore only be used to specify getter-only properties where the result of the getter is given by a single expression.

A *property_initializer* may only be given for an automatically implemented property ([Automatically implemented properties](#)), and causes the initialization of the underlying field of such properties with the value given by the *expression*.

Even though the syntax for accessing a property is the same as that for a field, a property is not classified as a variable. Thus, it is not possible to pass a property as a `ref` or `out` argument.

When a property declaration includes an `extern` modifier, the property is said to be an *external property*.

Because an external property declaration provides no actual implementation, each of its *accessor_declarations* consists of a semicolon.

Static and instance properties

When a property declaration includes a `static` modifier, the property is said to be a *static property*. When no `static` modifier is present, the property is said to be an *instance property*.

A static property is not associated with a specific instance, and it is a compile-time error to refer to `this` in the accessors of a static property.

An instance property is associated with a given instance of a class, and that instance can be accessed as `this` ([This access](#)) in the accessors of that property.

When a property is referenced in a *member_access* ([Member access](#)) of the form `E.M`, if `M` is a static property, `E` must denote a type containing `M`, and if `M` is an instance property, `E` must denote an instance of a type containing `M`.

The differences between static and instance members are discussed further in [Static and instance members](#).

Accessors

The *accessor_declarations* of a property specify the executable statements associated with reading and writing that property.

```
accessor_declarations
: get_accessor_declaration set_accessor_declaration?
| set_accessor_declaration get_accessor_declaration?
;

get_accessor_declaration
: attributes? accessor_modifier? 'get' accessor_body
;

set_accessor_declaration
: attributes? accessor_modifier? 'set' accessor_body
;

accessor_modifier
: 'protected'
| 'internal'
| 'private'
| 'protected' 'internal'
| 'internal' 'protected'
;

accessor_body
: block
| ';'
;
```

The accessor declarations consist of a *get_accessor_declaration*, a *set_accessor_declaration*, or both. Each accessor declaration consists of the token `get` or `set` followed by an optional *accessor_modifier* and an *accessor_body*.

The use of *accessor_modifiers* is governed by the following restrictions:

- An *accessor_modifier* may not be used in an interface or in an explicit interface member implementation.
- For a property or indexer that has no `override` modifier, an *accessor_modifier* is permitted only if the property or indexer has both a `get` and `set` accessor, and then is permitted only on one of those accessors.
- For a property or indexer that includes an `override` modifier, an accessor must match the *accessor_modifier*, if any, of the accessor being overridden.

- The *accessor_modifier* must declare an accessibility that is strictly more restrictive than the declared accessibility of the property or indexer itself. To be precise:
 - If the property or indexer has a declared accessibility of `public`, the *accessor_modifier* may be either `protected internal`, `internal`, `protected`, or `private`.
 - If the property or indexer has a declared accessibility of `protected internal`, the *accessor_modifier* may be either `internal`, `protected`, or `private`.
 - If the property or indexer has a declared accessibility of `internal` or `protected`, the *accessor_modifier* must be `private`.
 - If the property or indexer has a declared accessibility of `private`, no *accessor_modifier* may be used.

For `abstract` and `extern` properties, the *accessor_body* for each accessor specified is simply a semicolon. A non-abstract, non-extern property may have each *accessor_body* be a semicolon, in which case it is an **automatically implemented property** ([Automatically implemented properties](#)). An automatically implemented property must have at least a get accessor. For the accessors of any other non-abstract, non-extern property, the *accessor_body* is a *block* which specifies the statements to be executed when the corresponding accessor is invoked.

A `get` accessor corresponds to a parameterless method with a return value of the property type. Except as the target of an assignment, when a property is referenced in an expression, the `get` accessor of the property is invoked to compute the value of the property ([Values of expressions](#)). The body of a `get` accessor must conform to the rules for value-returning methods described in [Method body](#). In particular, all `return` statements in the body of a `get` accessor must specify an expression that is implicitly convertible to the property type. Furthermore, the endpoint of a `get` accessor must not be reachable.

A `set` accessor corresponds to a method with a single value parameter of the property type and a `void` return type. The implicit parameter of a `set` accessor is always named `value`. When a property is referenced as the target of an assignment ([Assignment operators](#)), or as the operand of `++` or `--` ([Postfix increment and decrement operators](#), [Prefix increment and decrement operators](#)), the `set` accessor is invoked with an argument (whose value is that of the right-hand side of the assignment or the operand of the `++` or `--` operator) that provides the new value ([Simple assignment](#)). The body of a `set` accessor must conform to the rules for `void` methods described in [Method body](#). In particular, `return` statements in the `set` accessor body are not permitted to specify an expression. Since a `set` accessor implicitly has a parameter named `value`, it is a compile-time error for a local variable or constant declaration in a `set` accessor to have that name.

Based on the presence or absence of the `get` and `set` accessors, a property is classified as follows:

- A property that includes both a `get` accessor and a `set` accessor is said to be a **read-write** property.
- A property that has only a `get` accessor is said to be a **read-only** property. It is a compile-time error for a read-only property to be the target of an assignment.
- A property that has only a `set` accessor is said to be a **write-only** property. Except as the target of an assignment, it is a compile-time error to reference a write-only property in an expression.

In the example

```

public class Button: Control
{
    private string caption;

    public string Caption {
        get {
            return caption;
        }
        set {
            if (caption != value) {
                caption = value;
                Repaint();
            }
        }
    }

    public override void Paint(Graphics g, Rectangle r) {
        // Painting code goes here
    }
}

```

the `Button` control declares a public `Caption` property. The `get` accessor of the `Caption` property returns the string stored in the private `caption` field. The `set` accessor checks if the new value is different from the current value, and if so, it stores the new value and repaints the control. Properties often follow the pattern shown above: The `get` accessor simply returns a value stored in a private field, and the `set` accessor modifies that private field and then performs any additional actions required to fully update the state of the object.

Given the `Button` class above, the following is an example of use of the `Caption` property:

```

Button okButton = new Button();
okButton.Caption = "OK";           // Invokes set accessor
string s = okButton.Caption;       // Invokes get accessor

```

Here, the `set` accessor is invoked by assigning a value to the property, and the `get` accessor is invoked by referencing the property in an expression.

The `get` and `set` accessors of a property are not distinct members, and it is not possible to declare the accessors of a property separately. As such, it is not possible for the two accessors of a read-write property to have different accessibility. The example

```

class A
{
    private string name;

    public string Name {                // Error, duplicate member name
        get { return name; }
    }

    public string Name {                // Error, duplicate member name
        set { name = value; }
    }
}

```

does not declare a single read-write property. Rather, it declares two properties with the same name, one read-only and one write-only. Since two members declared in the same class cannot have the same name, the example causes a compile-time error to occur.

When a derived class declares a property by the same name as an inherited property, the derived property hides the inherited property with respect to both reading and writing. In the example

```

class A
{
    public int P {
        set {...}
    }
}

class B: A
{
    new public int P {
        get {...}
    }
}

```

the `P` property in `B` hides the `P` property in `A` with respect to both reading and writing. Thus, in the statements

```

B b = new B();
b.P = 1;           // Error, B.P is read-only
((A)b).P = 1;      // Ok, reference to A.P

```

the assignment to `b.P` causes a compile-time error to be reported, since the read-only `P` property in `B` hides the write-only `P` property in `A`. Note, however, that a cast can be used to access the hidden `P` property.

Unlike public fields, properties provide a separation between an object's internal state and its public interface. Consider the example:

```

class Label
{
    private int x, y;
    private string caption;

    public Label(int x, int y, string caption) {
        this.x = x;
        this.y = y;
        this.caption = caption;
    }

    public int X {
        get { return x; }
    }

    public int Y {
        get { return y; }
    }

    public Point Location {
        get { return new Point(x, y); }
    }

    public string Caption {
        get { return caption; }
    }
}

```

Here, the `Label` class uses two `int` fields, `x` and `y`, to store its location. The location is publicly exposed both as an `X` and a `Y` property and as a `Location` property of type `Point`. If, in a future version of `Label`, it becomes more convenient to store the location as a `Point` internally, the change can be made without affecting the public interface of the class:

```

class Label
{
    private Point location;
    private string caption;

    public Label(int x, int y, string caption) {
        this.location = new Point(x, y);
        this.caption = caption;
    }

    public int X {
        get { return location.x; }
    }

    public int Y {
        get { return location.y; }
    }

    public Point Location {
        get { return location; }
    }

    public string Caption {
        get { return caption; }
    }
}

```

Had `x` and `y` instead been `public readonly` fields, it would have been impossible to make such a change to the `Label` class.

Exposing state through properties is not necessarily any less efficient than exposing fields directly. In particular, when a property is non-virtual and contains only a small amount of code, the execution environment may replace calls to accessors with the actual code of the accessors. This process is known as *inlining*, and it makes property access as efficient as field access, yet preserves the increased flexibility of properties.

Since invoking a `get` accessor is conceptually equivalent to reading the value of a field, it is considered bad programming style for `get` accessors to have observable side-effects. In the example

```

class Counter
{
    private int next;

    public int Next {
        get { return next++; }
    }
}

```

the value of the `Next` property depends on the number of times the property has previously been accessed. Thus, accessing the property produces an observable side-effect, and the property should be implemented as a method instead.

The "no side-effects" convention for `get` accessors doesn't mean that `get` accessors should always be written to simply return values stored in fields. Indeed, `get` accessors often compute the value of a property by accessing multiple fields or invoking methods. However, a properly designed `get` accessor performs no actions that cause observable changes in the state of the object.

Properties can be used to delay initialization of a resource until the moment it is first referenced. For example:

```

using System.IO;

public class Console
{
    private static TextReader reader;
    private static TextWriter writer;
    private static TextWriter error;

    public static TextReader In {
        get {
            if (reader == null) {
                reader = new StreamReader(Console.OpenStandardInput());
            }
            return reader;
        }
    }

    public static TextWriter Out {
        get {
            if (writer == null) {
                writer = new StreamWriter(Console.OpenStandardOutput());
            }
            return writer;
        }
    }

    public static TextWriter Error {
        get {
            if (error == null) {
                error = new StreamWriter(Console.OpenStandardError());
            }
            return error;
        }
    }
}

```

The `Console` class contains three properties, `In`, `Out`, and `Error`, that represent the standard input, output, and error devices, respectively. By exposing these members as properties, the `Console` class can delay their initialization until they are actually used. For example, upon first referencing the `Out` property, as in

```
Console.Out.WriteLine("hello, world");
```

the underlying `TextWriter` for the output device is created. But if the application makes no reference to the `In` and `Error` properties, then no objects are created for those devices.

Automatically implemented properties

An automatically implemented property (or *auto-property* for short), is a non-abstract non-extern property with semicolon-only accessor bodies. Auto-properties must have a get accessor and can optionally have a set accessor.

When a property is specified as an automatically implemented property, a hidden backing field is automatically available for the property, and the accessors are implemented to read from and write to that backing field. If the auto-property has no set accessor, the backing field is considered `readonly` ([Readonly fields](#)). Just like a `readonly` field, a getter-only auto-property can also be assigned to in the body of a constructor of the enclosing class. Such an assignment assigns directly to the readonly backing field of the property.

An auto-property may optionally have a *property_initializer*, which is applied directly to the backing field as a *variable_initializer* ([Variable initializers](#)).

The following example:

```
public class Point {
    public int X { get; set; } = 0;
    public int Y { get; set; } = 0;
}
```

is equivalent to the following declaration:

```
public class Point {
    private int __x = 0;
    private int __y = 0;
    public int X { get { return __x; } set { __x = value; } }
    public int Y { get { return __y; } set { __y = value; } }
}
```

The following example:

```
public class ReadOnlyPoint
{
    public int X { get; }
    public int Y { get; }
    public ReadOnlyPoint(int x, int y) { X = x; Y = y; }
}
```

is equivalent to the following declaration:

```
public class ReadOnlyPoint
{
    private readonly int __x;
    private readonly int __y;
    public int X { get { return __x; } }
    public int Y { get { return __y; } }
    public ReadOnlyPoint(int x, int y) { __x = x; __y = y; }
}
```

Notice that the assignments to the readonly field are legal, because they occur within the constructor.

Accessibility

If an accessor has an *accessor_modifier*, the accessibility domain ([Accessibility domains](#)) of the accessor is determined using the declared accessibility of the *accessor_modifier*. If an accessor does not have an *accessor_modifier*, the accessibility domain of the accessor is determined from the declared accessibility of the property or indexer.

The presence of an *accessor_modifier* never affects member lookup ([Operators](#)) or overload resolution ([Overload resolution](#)). The modifiers on the property or indexer always determine which property or indexer is bound to, regardless of the context of the access.

Once a particular property or indexer has been selected, the accessibility domains of the specific accessors involved are used to determine if that usage is valid:

- If the usage is as a value ([Values of expressions](#)), the `get` accessor must exist and be accessible.
- If the usage is as the target of a simple assignment ([Simple assignment](#)), the `set` accessor must exist and be accessible.
- If the usage is as the target of compound assignment ([Compound assignment](#)), or as the target of the `++` or `--` operators ([Function members.9](#), [Invocation expressions](#)), both the `get` accessors and the `set` accessor must exist and be accessible.

In the following example, the property `A.Text` is hidden by the property `B.Text`, even in contexts where only the `set` accessor is called. In contrast, the property `B.Count` is not accessible to class `M`, so the accessible property `A.Count` is used instead.

```
class A
{
    public string Text {
        get { return "hello"; }
        set { }
    }

    public int Count {
        get { return 5; }
        set { }
    }
}

class B: A
{
    private string text = "goodbye";
    private int count = 0;

    new public string Text {
        get { return text; }
        protected set { text = value; }
    }

    new protected int Count {
        get { return count; }
        set { count = value; }
    }
}

class M
{
    static void Main() {
        B b = new B();
        b.Count = 12;           // Calls A.Count set accessor
        int i = b.Count;        // Calls A.Count get accessor
        b.Text = "howdy";       // Error, B.Text set accessor not accessible
        string s = b.Text;      // Calls B.Text get accessor
    }
}
```

An accessor that is used to implement an interface may not have an *accessor_modifier*. If only one accessor is used to implement an interface, the other accessor may be declared with an *accessor_modifier*.

```
public interface I
{
    string Prop { get; }
}

public class C: I
{
    public string Prop {
        get { return "April"; }           // Must not have a modifier here
        internal set {...}                // Ok, because I.Prop has no set accessor
    }
}
```

Virtual, sealed, override, and abstract property accessors

A `virtual` property declaration specifies that the accessors of the property are virtual. The `virtual` modifier

applies to both accessors of a read-write property—it is not possible for only one accessor of a read-write property to be virtual.

An `abstract` property declaration specifies that the accessors of the property are virtual, but does not provide an actual implementation of the accessors. Instead, non-abstract derived classes are required to provide their own implementation for the accessors by overriding the property. Because an accessor for an abstract property declaration provides no actual implementation, its *accessor_body* simply consists of a semicolon.

A property declaration that includes both the `abstract` and `override` modifiers specifies that the property is abstract and overrides a base property. The accessors of such a property are also abstract.

Abstract property declarations are only permitted in abstract classes ([Abstract classes](#)). The accessors of an inherited virtual property can be overridden in a derived class by including a property declaration that specifies an `override` directive. This is known as an **overriding property declaration**. An overriding property declaration does not declare a new property. Instead, it simply specializes the implementations of the accessors of an existing virtual property.

An overriding property declaration must specify the exact same accessibility modifiers, type, and name as the inherited property. If the inherited property has only a single accessor (i.e., if the inherited property is read-only or write-only), the overriding property must include only that accessor. If the inherited property includes both accessors (i.e., if the inherited property is read-write), the overriding property can include either a single accessor or both accessors.

An overriding property declaration may include the `sealed` modifier. Use of this modifier prevents a derived class from further overriding the property. The accessors of a sealed property are also sealed.

Except for differences in declaration and invocation syntax, virtual, sealed, override, and abstract accessors behave exactly like virtual, sealed, override and abstract methods. Specifically, the rules described in [Virtual methods](#), [Override methods](#), [Sealed methods](#), and [Abstract methods](#) apply as if accessors were methods of a corresponding form:

- A `get` accessor corresponds to a parameterless method with a return value of the property type and the same modifiers as the containing property.
- A `set` accessor corresponds to a method with a single value parameter of the property type, a `void` return type, and the same modifiers as the containing property.

In the example

```
abstract class A
{
    int y;

    public virtual int X {
        get { return 0; }
    }

    public virtual int Y {
        get { return y; }
        set { y = value; }
    }

    public abstract int Z { get; set; }
}
```

`X` is a virtual read-only property, `Y` is a virtual read-write property, and `Z` is an abstract read-write property. Because `Z` is abstract, the containing class `A` must also be declared abstract.

A class that derives from `A` is shown below:

```

class B: A
{
    int z;

    public override int X {
        get { return base.X + 1; }
    }

    public override int Y {
        set { base.Y = value < 0? 0: value; }
    }

    public override int Z {
        get { return z; }
        set { z = value; }
    }
}

```

Here, the declarations of `X`, `Y`, and `Z` are overriding property declarations. Each property declaration exactly matches the accessibility modifiers, type, and name of the corresponding inherited property. The `get` accessor of `X` and the `set` accessor of `Y` use the `base` keyword to access the inherited accessors. The declaration of `Z` overrides both abstract accessors—thus, there are no outstanding abstract function members in `B`, and `B` is permitted to be a non-abstract class.

When a property is declared as an `override`, any overridden accessors must be accessible to the overriding code. In addition, the declared accessibility of both the property or indexer itself, and of the accessors, must match that of the overridden member and accessors. For example:

```

public class B
{
    public virtual int P {
        protected set {...}
        get {...}
    }
}

public class D: B
{
    public override int P {
        protected set {...}           // Must specify protected here
        get {...}                     // Must not have a modifier here
    }
}

```

Events

An **event** is a member that enables an object or class to provide notifications. Clients can attach executable code for events by supplying **event handlers**.

Events are declared using *event declarations*:

```

event_declaration
  : attributes? event_modifier* 'event' type variable_declarators ';'
  | attributes? event_modifier* 'event' type member_name '{' event_accessor_declarations '}'
  ;

event_modifier
  : 'new'
  | 'public'
  | 'protected'
  | 'internal'
  | 'private'
  | 'static'
  | 'virtual'
  | 'sealed'
  | 'override'
  | 'abstract'
  | 'extern'
  | event_modifier_unsafe
  ;

event_accessor_declarations
  : add_accessor_declaration remove_accessor_declaration
  | remove_accessor_declaration add_accessor_declaration
  ;

add_accessor_declaration
  : attributes? 'add' block
  ;

remove_accessor_declaration
  : attributes? 'remove' block
  ;

```

An *event_declaration* may include a set of *attributes* ([Attributes](#)) and a valid combination of the four access modifiers ([Access modifiers](#)), the `new` ([The new modifier](#)), `static` ([Static and instance methods](#)), `virtual` ([Virtual methods](#)), `override` ([Override methods](#)), `sealed` ([Sealed methods](#)), `abstract` ([Abstract methods](#)), and `extern` ([External methods](#)) modifiers.

Event declarations are subject to the same rules as method declarations ([Methods](#)) with regard to valid combinations of modifiers.

The *type* of an event declaration must be a *delegate_type* ([Reference types](#)), and that *delegate_type* must be at least as accessible as the event itself ([Accessibility constraints](#)).

An event declaration may include *event_accessor_declarations*. However, if it does not, for non-extern, non-abstract events, the compiler supplies them automatically ([Field-like events](#)); for extern events, the accessors are provided externally.

An event declaration that omits *event_accessor_declarations* defines one or more events—one for each of the *variable_declarators*. The attributes and modifiers apply to all of the members declared by such an *event_declaration*.

It is a compile-time error for an *event_declaration* to include both the `abstract` modifier and brace-delimited *event_accessor_declarations*.

When an event declaration includes an `extern` modifier, the event is said to be an **external event**. Because an external event declaration provides no actual implementation, it is an error for it to include both the `extern` modifier and *event_accessor_declarations*.

It is a compile-time error for a *variable_declarator* of an event declaration with an `abstract` or `external` modifier to include a *variable_initializer*.

An event can be used as the left-hand operand of the `+=` and `-=` operators ([Event assignment](#)). These operators are used, respectively, to attach event handlers to or to remove event handlers from an event, and the access modifiers of the event control the contexts in which such operations are permitted.

Since `+=` and `-=` are the only operations that are permitted on an event outside the type that declares the event, external code can add and remove handlers for an event, but cannot in any other way obtain or modify the underlying list of event handlers.

In an operation of the form `x += y` or `x -= y`, when `x` is an event and the reference takes place outside the type that contains the declaration of `x`, the result of the operation has type `void` (as opposed to having the type of `x`, with the value of `x` after the assignment). This rule prohibits external code from indirectly examining the underlying delegate of an event.

The following example shows how event handlers are attached to instances of the `Button` class:

```
public delegate void EventHandler(object sender, EventArgs e);

public class Button: Control
{
    public event EventHandler Click;
}

public class LoginDialog: Form
{
    Button OkButton;
    Button CancelButton;

    public LoginDialog() {
        OkButton = new Button(...);
        OkButton.Click += new EventHandler(OkButtonClick);
        CancelButton = new Button(...);
        CancelButton.Click += new EventHandler(CancelButtonClick);
    }

    void OkButtonClick(object sender, EventArgs e) {
        // Handle OkButton.Click event
    }

    void CancelButtonClick(object sender, EventArgs e) {
        // Handle CancelButton.Click event
    }
}
```

Here, the `LoginDialog` instance constructor creates two `Button` instances and attaches event handlers to the `Click` events.

Field-like events

Within the program text of the class or struct that contains the declaration of an event, certain events can be used like fields. To be used in this way, an event must not be `abstract` or `extern`, and must not explicitly include *event_accessor_declarations*. Such an event can be used in any context that permits a field. The field contains a delegate ([Delegates](#)) which refers to the list of event handlers that have been added to the event. If no event handlers have been added, the field contains `null`.

In the example

```

public delegate void EventHandler(object sender, EventArgs e);

public class Button: Control
{
    public event EventHandler Click;

    protected void OnClick(EventArgs e) {
        if (Click != null) Click(this, e);
    }

    public void Reset() {
        Click = null;
    }
}

```

`Click` is used as a field within the `Button` class. As the example demonstrates, the field can be examined, modified, and used in delegate invocation expressions. The `OnClick` method in the `Button` class "raises" the `Click` event. The notion of raising an event is precisely equivalent to invoking the delegate represented by the event—thus, there are no special language constructs for raising events. Note that the delegate invocation is preceded by a check that ensures the delegate is non-null.

Outside the declaration of the `Button` class, the `Click` member can only be used on the left-hand side of the `+=` and `-=` operators, as in

```
b.Click += new EventHandler(...);
```

which appends a delegate to the invocation list of the `Click` event, and

```
b.Click -= new EventHandler(...);
```

which removes a delegate from the invocation list of the `Click` event.

When compiling a field-like event, the compiler automatically creates storage to hold the delegate, and creates accessors for the event that add or remove event handlers to the delegate field. The addition and removal operations are thread safe, and may (but are not required to) be done while holding the lock ([The lock statement](#)) on the containing object for an instance event, or the type object ([Anonymous object creation expressions](#)) for a static event.

Thus, an instance event declaration of the form:

```

class X
{
    public event D Ev;
}

```

will be compiled to something equivalent to:

```

class X
{
    private D __Ev; // field to hold the delegate

    public event D Ev {
        add {
            /* add the delegate in a thread safe way */
        }

        remove {
            /* remove the delegate in a thread safe way */
        }
    }
}

```

Within the class `X`, references to `Ev` on the left-hand side of the `+=` and `-=` operators cause the add and remove accessors to be invoked. All other references to `Ev` are compiled to reference the hidden field `__Ev` instead ([Member access](#)). The name "`__Ev`" is arbitrary; the hidden field could have any name or no name at all.

Event accessors

Event declarations typically omit *event_accessor_declarations*, as in the `Button` example above. One situation for doing so involves the case in which the storage cost of one field per event is not acceptable. In such cases, a class can include *event_accessor_declarations* and use a private mechanism for storing the list of event handlers.

The *event_accessor_declarations* of an event specify the executable statements associated with adding and removing event handlers.

The accessor declarations consist of an *add_accessor_declaration* and a *remove_accessor_declaration*. Each accessor declaration consists of the token `add` or `remove` followed by a *block*. The *block* associated with an *add_accessor_declaration* specifies the statements to execute when an event handler is added, and the *block* associated with a *remove_accessor_declaration* specifies the statements to execute when an event handler is removed.

Each *add_accessor_declaration* and *remove_accessor_declaration* corresponds to a method with a single value parameter of the event type and a `void` return type. The implicit parameter of an event accessor is named `value`. When an event is used in an event assignment, the appropriate event accessor is used. Specifically, if the assignment operator is `+=` then the add accessor is used, and if the assignment operator is `-=` then the remove accessor is used. In either case, the right-hand operand of the assignment operator is used as the argument to the event accessor. The block of an *add_accessor_declaration* or a *remove_accessor_declaration* must conform to the rules for `void` methods described in [Method body](#). In particular, `return` statements in such a block are not permitted to specify an expression.

Since an event accessor implicitly has a parameter named `value`, it is a compile-time error for a local variable or constant declared in an event accessor to have that name.

In the example

```

class Control: Component
{
    // Unique keys for events
    static readonly object mouseDownEventKey = new object();
    static readonly object mouseUpEventKey = new object();

    // Return event handler associated with key
    protected Delegate GetEventHandler(object key) {...}

    // Add event handler associated with key
    protected void AddEventHandler(object key, Delegate handler) {...}

    // Remove event handler associated with key
    protected void RemoveEventHandler(object key, Delegate handler) {...}

    // MouseDown event
    public event MouseEventHandler MouseDown {
        add { AddEventHandler(mouseDownEventKey, value); }
        remove { RemoveEventHandler(mouseDownEventKey, value); }
    }

    // MouseUp event
    public event MouseEventHandler MouseUp {
        add { AddEventHandler(mouseUpEventKey, value); }
        remove { RemoveEventHandler(mouseUpEventKey, value); }
    }

    // Invoke the MouseUp event
    protected void OnMouseUp(MouseEventArgs args) {
        MouseEventHandler handler;
        handler = (MouseEventHandler)GetEventHandler(mouseUpEventKey);
        if (handler != null)
            handler(this, args);
    }
}

```

the `Control` class implements an internal storage mechanism for events. The `AddEventHandler` method associates a delegate value with a key, the `GetEventHandler` method returns the delegate currently associated with a key, and the `RemoveEventHandler` method removes a delegate as an event handler for the specified event. Presumably, the underlying storage mechanism is designed such that there is no cost for associating a `null` delegate value with a key, and thus unhandled events consume no storage.

Static and instance events

When an event declaration includes a `static` modifier, the event is said to be a *static event*. When no `static` modifier is present, the event is said to be an *instance event*.

A static event is not associated with a specific instance, and it is a compile-time error to refer to `this` in the accessors of a static event.

An instance event is associated with a given instance of a class, and this instance can be accessed as `this` ([This access](#)) in the accessors of that event.

When an event is referenced in a *member access* ([Member access](#)) of the form `E.M`, if `M` is a static event, `E` must denote a type containing `M`, and if `M` is an instance event, `E` must denote an instance of a type containing `M`.

The differences between static and instance members are discussed further in [Static and instance members](#).

Virtual, sealed, override, and abstract event accessors

A `virtual` event declaration specifies that the accessors of that event are virtual. The `virtual` modifier applies to both accessors of an event.

An `abstract` event declaration specifies that the accessors of the event are virtual, but does not provide an actual implementation of the accessors. Instead, non-abstract derived classes are required to provide their own implementation for the accessors by overriding the event. Because an abstract event declaration provides no actual implementation, it cannot provide brace-delimited *event_accessor_declarations*.

An event declaration that includes both the `abstract` and `override` modifiers specifies that the event is abstract and overrides a base event. The accessors of such an event are also abstract.

Abstract event declarations are only permitted in abstract classes ([Abstract classes](#)).

The accessors of an inherited virtual event can be overridden in a derived class by including an event declaration that specifies an `override` modifier. This is known as an ***overriding event declaration***. An overriding event declaration does not declare a new event. Instead, it simply specializes the implementations of the accessors of an existing virtual event.

An overriding event declaration must specify the exact same accessibility modifiers, type, and name as the overridden event.

An overriding event declaration may include the `sealed` modifier. Use of this modifier prevents a derived class from further overriding the event. The accessors of a sealed event are also sealed.

It is a compile-time error for an overriding event declaration to include a `new` modifier.

Except for differences in declaration and invocation syntax, virtual, sealed, override, and abstract accessors behave exactly like virtual, sealed, override and abstract methods. Specifically, the rules described in [Virtual methods](#), [Override methods](#), [Sealed methods](#), and [Abstract methods](#) apply as if accessors were methods of a corresponding form. Each accessor corresponds to a method with a single value parameter of the event type, a `void` return type, and the same modifiers as the containing event.

Indexers

An ***indexer*** is a member that enables an object to be indexed in the same way as an array. Indexers are declared using *indexer_declarations*:

```

indexer_declaration
: attributes? indexer_modifier* indexer_declarator indexer_body
;

indexer_modifier
: 'new'
| 'public'
| 'protected'
| 'internal'
| 'private'
| 'virtual'
| 'sealed'
| 'override'
| 'abstract'
| 'extern'
| indexer_modifier_unsafe
;

indexer_declarator
: type 'this' '[' formal_parameter_list '['
| type interface_type '.' 'this' '[' formal_parameter_list '['
;

indexer_body
: '{' accessor_declarations '}'
| '=>' expression ';'
;

```

An *indexer_declaration* may include a set of *attributes* ([Attributes](#)) and a valid combination of the four access modifiers ([Access modifiers](#)), the `new` ([The new modifier](#)), `virtual` ([Virtual methods](#)), `override` ([Override methods](#)), `sealed` ([Sealed methods](#)), `abstract` ([Abstract methods](#)), and `extern` ([External methods](#)) modifiers.

Indexer declarations are subject to the same rules as method declarations ([Methods](#)) with regard to valid combinations of modifiers, with the one exception being that the static modifier is not permitted on an indexer declaration.

The modifiers `virtual`, `override`, and `abstract` are mutually exclusive except in one case. The `abstract` and `override` modifiers may be used together so that an abstract indexer can override a virtual one.

The *type* of an indexer declaration specifies the element type of the indexer introduced by the declaration. Unless the indexer is an explicit interface member implementation, the *type* is followed by the keyword `this`. For an explicit interface member implementation, the *type* is followed by an *interface_type*, a `.`, and the keyword `this`. Unlike other members, indexers do not have user-defined names.

The *formal_parameter_list* specifies the parameters of the indexer. The formal parameter list of an indexer corresponds to that of a method ([Method parameters](#)), except that at least one parameter must be specified, and that the `ref` and `out` parameter modifiers are not permitted.

The *type* of an indexer and each of the types referenced in the *formal_parameter_list* must be at least as accessible as the indexer itself ([Accessibility constraints](#)).

An *indexer_body* may either consist of an *accessor body* or an *expression body*. In an accessor body, *accessor_declarations*, which must be enclosed in `{` and `}` tokens, declare the accessors ([Accessors](#)) of the property. The accessors specify the executable statements associated with reading and writing the property.

An expression body consisting of `=>` followed by an expression `E` and a semicolon is exactly equivalent to the statement body `{ get { return E; } }`, and can therefore only be used to specify getter-only indexers where the result of the getter is given by a single expression.

Even though the syntax for accessing an indexer element is the same as that for an array element, an indexer

element is not classified as a variable. Thus, it is not possible to pass an indexer element as a `ref` or `out` argument.

The formal parameter list of an indexer defines the signature ([Signatures and overloading](#)) of the indexer. Specifically, the signature of an indexer consists of the number and types of its formal parameters. The element type and names of the formal parameters are not part of an indexer's signature.

The signature of an indexer must differ from the signatures of all other indexers declared in the same class.

Indexers and properties are very similar in concept, but differ in the following ways:

- A property is identified by its name, whereas an indexer is identified by its signature.
- A property is accessed through a *simple_name* ([Simple names](#)) or a *member_access* ([Member access](#)), whereas an indexer element is accessed through an *element_access* ([Indexer access](#)).
- A property can be a `static` member, whereas an indexer is always an instance member.
- A `get` accessor of a property corresponds to a method with no parameters, whereas a `get` accessor of an indexer corresponds to a method with the same formal parameter list as the indexer.
- A `set` accessor of a property corresponds to a method with a single parameter named `value`, whereas a `set` accessor of an indexer corresponds to a method with the same formal parameter list as the indexer, plus an additional parameter named `value`.
- It is a compile-time error for an indexer accessor to declare a local variable with the same name as an indexer parameter.
- In an overriding property declaration, the inherited property is accessed using the syntax `base.P`, where `P` is the property name. In an overriding indexer declaration, the inherited indexer is accessed using the syntax `base[E]`, where `E` is a comma separated list of expressions.
- There is no concept of an "automatically implemented indexer". It is an error to have a non-abstract, non-external indexer with semicolon accessors.

Aside from these differences, all rules defined in [Accessors](#) and [Automatically implemented properties](#) apply to indexer accessors as well as to property accessors.

When an indexer declaration includes an `extern` modifier, the indexer is said to be an ***external indexer***. Because an external indexer declaration provides no actual implementation, each of its *accessor_declarations* consists of a semicolon.

The example below declares a `BitArray` class that implements an indexer for accessing the individual bits in the bit array.

```

using System;

class BitArray
{
    int[] bits;
    int length;

    public BitArray(int length) {
        if (length < 0) throw new ArgumentException();
        bits = new int[((length - 1) >> 5) + 1];
        this.length = length;
    }

    public int Length {
        get { return length; }
    }

    public bool this[int index] {
        get {
            if (index < 0 || index >= length) {
                throw new IndexOutOfRangeException();
            }
            return (bits[index >> 5] & 1 << index) != 0;
        }
        set {
            if (index < 0 || index >= length) {
                throw new IndexOutOfRangeException();
            }
            if (value) {
                bits[index >> 5] |= 1 << index;
            }
            else {
                bits[index >> 5] &= ~(1 << index);
            }
        }
    }
}

```

An instance of the `BitArray` class consumes substantially less memory than a corresponding `bool[]` (since each value of the former occupies only one bit instead of the latter's one byte), but it permits the same operations as a `bool[]`.

The following `CountPrimes` class uses a `BitArray` and the classical "sieve" algorithm to compute the number of primes between 1 and a given maximum:

```

class CountPrimes
{
    static int Count(int max) {
        BitArray flags = new BitArray(max + 1);
        int count = 1;
        for (int i = 2; i <= max; i++) {
            if (!flags[i]) {
                for (int j = i * 2; j <= max; j += i) flags[j] = true;
                count++;
            }
        }
        return count;
    }

    static void Main(string[] args) {
        int max = int.Parse(args[0]);
        int count = Count(max);
        Console.WriteLine("Found {0} primes between 1 and {1}", count, max);
    }
}

```

Note that the syntax for accessing elements of the `BitArray` is precisely the same as for a `bool[]`.

The following example shows a 26 * 10 grid class that has an indexer with two parameters. The first parameter is required to be an upper- or lowercase letter in the range A-Z, and the second is required to be an integer in the range 0-9.

```

using System;

class Grid
{
    const int NumRows = 26;
    const int NumCols = 10;

    int[, ] cells = new int[NumRows, NumCols];

    public int this[char c, int col] {
        get {
            c = Char.ToUpper(c);
            if (c < 'A' || c > 'Z') {
                throw new ArgumentException();
            }
            if (col < 0 || col >= NumCols) {
                throw new IndexOutOfRangeException();
            }
            return cells[c - 'A', col];
        }

        set {
            c = Char.ToUpper(c);
            if (c < 'A' || c > 'Z') {
                throw new ArgumentException();
            }
            if (col < 0 || col >= NumCols) {
                throw new IndexOutOfRangeException();
            }
            cells[c - 'A', col] = value;
        }
    }
}

```

Indexer overloading

The indexer overload resolution rules are described in [Type inference](#).

Operators

An ***operator*** is a member that defines the meaning of an expression operator that can be applied to instances of the class. Operators are declared using *operator_declarations*:

```
operator_declaration
: attributes? operator_modifier+ operator_declarator operator_body
;

operator_modifier
: 'public'
| 'static'
| 'extern'
| operator_modifier_unsafe
;

operator_declarator
: unary_operator_declarator
| binary_operator_declarator
| conversion_operator_declarator
;

unary_operator_declarator
: type 'operator' overloadable_unary_operator '(' type identifier ')'
;

overloadable_unary_operator
: '+' | '-' | '!' | '~' | '++' | '--' | 'true' | 'false'
;

binary_operator_declarator
: type 'operator' overloadable_binary_operator '(' type identifier ',' type identifier ')'
;

overloadable_binary_operator
: '+' | '-' | '*' | '/' | '%' | '&' | '|' | '^' | '<<'
| right_shift | '==' | '!=' | '>' | '<' | '>=' | '<='
;

conversion_operator_declarator
: 'implicit' 'operator' type '(' type identifier ')'
| 'explicit' 'operator' type '(' type identifier ')'
;

operator_body
: block
| '=>' expression ';'
| ';'
;
```

There are three categories of overloadable operators: Unary operators ([Unary operators](#)), binary operators ([Binary operators](#)), and conversion operators ([Conversion operators](#)).

The *operator_body* is either a semicolon, a ***statement body*** or an ***expression body***. A statement body consists of a *block*, which specifies the statements to execute when the operator is invoked. The *block* must conform to the rules for value-returning methods described in [Method body](#). An expression body consists of `=>` followed by an expression and a semicolon, and denotes a single expression to perform when the operator is invoked.

For `extern` operators, the *operator_body* consists simply of a semicolon. For all other operators, the *operator_body* is either a block body or an expression body.

The following rules apply to all operator declarations:

- An operator declaration must include both a `public` and a `static` modifier.
- The parameter(s) of an operator must be value parameters ([Value parameters](#)). It is a compile-time error for an operator declaration to specify `ref` or `out` parameters.
- The signature of an operator ([Unary operators](#), [Binary operators](#), [Conversion operators](#)) must differ from the signatures of all other operators declared in the same class.
- All types referenced in an operator declaration must be at least as accessible as the operator itself ([Accessibility constraints](#)).
- It is an error for the same modifier to appear multiple times in an operator declaration.

Each operator category imposes additional restrictions, as described in the following sections.

Like other members, operators declared in a base class are inherited by derived classes. Because operator declarations always require the class or struct in which the operator is declared to participate in the signature of the operator, it is not possible for an operator declared in a derived class to hide an operator declared in a base class. Thus, the `new` modifier is never required, and therefore never permitted, in an operator declaration.

Additional information on unary and binary operators can be found in [Operators](#).

Additional information on conversion operators can be found in [User-defined conversions](#).

Unary operators

The following rules apply to unary operator declarations, where `T` denotes the instance type of the class or struct that contains the operator declaration:

- A unary `+`, `-`, `!`, or `~` operator must take a single parameter of type `T` or `T?` and can return any type.
- A unary `++` or `--` operator must take a single parameter of type `T` or `T?` and must return that same type or a type derived from it.
- A unary `true` or `false` operator must take a single parameter of type `T` or `T?` and must return type `bool`.

The signature of a unary operator consists of the operator token (`+`, `-`, `!`, `~`, `++`, `--`, `true`, or `false`) and the type of the single formal parameter. The return type is not part of a unary operator's signature, nor is the name of the formal parameter.

The `true` and `false` unary operators require pair-wise declaration. A compile-time error occurs if a class declares one of these operators without also declaring the other. The `true` and `false` operators are described further in [User-defined conditional logical operators](#) and [Boolean expressions](#).

The following example shows an implementation and subsequent usage of `operator ++` for an integer vector class:

```

public class IntVector
{
    public IntVector(int length) {...}

    public int Length {...}           // read-only property

    public int this[int index] {...}   // read-write indexer

    public static IntVector operator ++(IntVector iv) {
        IntVector temp = new IntVector(iv.Length);
        for (int i = 0; i < iv.Length; i++)
            temp[i] = iv[i] + 1;
        return temp;
    }
}

class Test
{
    static void Main() {
        IntVector iv1 = new IntVector(4);    // vector of 4 x 0
        IntVector iv2;

        iv2 = iv1++;    // iv2 contains 4 x 0, iv1 contains 4 x 1
        iv2 = ++iv1;     // iv2 contains 4 x 2, iv1 contains 4 x 2
    }
}

```

Note how the operator method returns the value produced by adding 1 to the operand, just like the postfix increment and decrement operators ([Postfix increment and decrement operators](#)), and the prefix increment and decrement operators ([Prefix increment and decrement operators](#)). Unlike in C++, this method need not modify the value of its operand directly. In fact, modifying the operand value would violate the standard semantics of the postfix increment operator.

Binary operators

The following rules apply to binary operator declarations, where `T` denotes the instance type of the class or struct that contains the operator declaration:

- A binary non-shift operator must take two parameters, at least one of which must have type `T` or `T?`, and can return any type.
- A binary `<<` or `>>` operator must take two parameters, the first of which must have type `T` or `T?` and the second of which must have type `int` or `int?`, and can return any type.

The signature of a binary operator consists of the operator token (`+`, `-`, `*`, `/`, `%`, `&`, `|`, `^`, `<<`, `>>`, `==`, `!=`, `>`, `<`, `>=`, or `<=`) and the types of the two formal parameters. The return type and the names of the formal parameters are not part of a binary operator's signature.

Certain binary operators require pair-wise declaration. For every declaration of either operator of a pair, there must be a matching declaration of the other operator of the pair. Two operator declarations match when they have the same return type and the same type for each parameter. The following operators require pair-wise declaration:

- `operator ==` and `operator !=`
- `operator >` and `operator <`
- `operator >=` and `operator <=`

Conversion operators

A conversion operator declaration introduces a *user-defined conversion* ([User-defined conversions](#)) which augments the pre-defined implicit and explicit conversions.

A conversion operator declaration that includes the `implicit` keyword introduces a user-defined implicit conversion. Implicit conversions can occur in a variety of situations, including function member invocations, cast expressions, and assignments. This is described further in [Implicit conversions](#).

A conversion operator declaration that includes the `explicit` keyword introduces a user-defined explicit conversion. Explicit conversions can occur in cast expressions, and are described further in [Explicit conversions](#).

A conversion operator converts from a source type, indicated by the parameter type of the conversion operator, to a target type, indicated by the return type of the conversion operator.

For a given source type `S` and target type `T`, if `S` or `T` are nullable types, let `S0` and `T0` refer to their underlying types, otherwise `S0` and `T0` are equal to `S` and `T` respectively. A class or struct is permitted to declare a conversion from a source type `S` to a target type `T` only if all of the following are true:

- `S0` and `T0` are different types.
- Either `S0` or `T0` is the class or struct type in which the operator declaration takes place.
- Neither `S0` nor `T0` is an *interface_type*.
- Excluding user-defined conversions, a conversion does not exist from `S` to `T` or from `T` to `S`.

For the purposes of these rules, any type parameters associated with `S` or `T` are considered to be unique types that have no inheritance relationship with other types, and any constraints on those type parameters are ignored.

In the example

```
class C<T> {...}

class D<T>: C<T>
{
    public static implicit operator C<int>(D<T> value) {...}    // Ok
    public static implicit operator C<string>(D<T> value) {...} // Ok
    public static implicit operator C<T>(D<T> value) {...}     // Error
}
```

the first two operator declarations are permitted because, for the purposes of [Indexers.3](#), `T` and `int` and `string` respectively are considered unique types with no relationship. However, the third operator is an error because `C<T>` is the base class of `D<T>`.

From the second rule it follows that a conversion operator must convert either to or from the class or struct type in which the operator is declared. For example, it is possible for a class or struct type `C` to define a conversion from `C` to `int` and from `int` to `C`, but not from `int` to `bool`.

It is not possible to directly redefine a pre-defined conversion. Thus, conversion operators are not allowed to convert from or to `object` because implicit and explicit conversions already exist between `object` and all other types. Likewise, neither the source nor the target types of a conversion can be a base type of the other, since a conversion would then already exist.

However, it is possible to declare operators on generic types that, for particular type arguments, specify conversions that already exist as pre-defined conversions. In the example

```
struct Convertible<T>
{
    public static implicit operator Convertible<T>(T value) {...}
    public static explicit operator T(Convertible<T> value) {...}
}
```

when type `object` is specified as a type argument for `T`, the second operator declares a conversion that

already exists (an implicit, and therefore also an explicit, conversion exists from any type `object`).

In cases where a pre-defined conversion exists between two types, any user-defined conversions between those types are ignored. Specifically:

- If a pre-defined implicit conversion ([Implicit conversions](#)) exists from type `S` to type `T`, all user-defined conversions (implicit or explicit) from `S` to `T` are ignored.
- If a pre-defined explicit conversion ([Explicit conversions](#)) exists from type `S` to type `T`, any user-defined explicit conversions from `S` to `T` are ignored. Furthermore:

If `T` is an interface type, user-defined implicit conversions from `S` to `T` are ignored.

Otherwise, user-defined implicit conversions from `S` to `T` are still considered.

For all types but `object`, the operators declared by the `Convertible<T>` type above do not conflict with pre-defined conversions. For example:

```
void F(int i, Convertible<int> n) {
    i = n;                // Error
    i = (int)n;           // User-defined explicit conversion
    n = i;                // User-defined implicit conversion
    n = (Convertible<int>)i; // User-defined implicit conversion
}
```

However, for type `object`, pre-defined conversions hide the user-defined conversions in all cases but one:

```
void F(object o, Convertible<object> n) {
    o = n;                // Pre-defined boxing conversion
    o = (object)n;        // Pre-defined boxing conversion
    n = o;                // User-defined implicit conversion
    n = (Convertible<object>)o; // Pre-defined unboxing conversion
}
```

User-defined conversions are not allowed to convert from or to *interface_types*. In particular, this restriction ensures that no user-defined transformations occur when converting to an *interface_type*, and that a conversion to an *interface_type* succeeds only if the object being converted actually implements the specified *interface_type*.

The signature of a conversion operator consists of the source type and the target type. (Note that this is the only form of member for which the return type participates in the signature.) The `implicit` or `explicit` classification of a conversion operator is not part of the operator's signature. Thus, a class or struct cannot declare both an `implicit` and an `explicit` conversion operator with the same source and target types.

In general, user-defined implicit conversions should be designed to never throw exceptions and never lose information. If a user-defined conversion can give rise to exceptions (for example, because the source argument is out of range) or loss of information (such as discarding high-order bits), then that conversion should be defined as an explicit conversion.

In the example

```

using System;

public struct Digit
{
    byte value;

    public Digit(byte value) {
        if (value < 0 || value > 9) throw new ArgumentException();
        this.value = value;
    }

    public static implicit operator byte(Digit d) {
        return d.value;
    }

    public static explicit operator Digit(byte b) {
        return new Digit(b);
    }
}

```

the conversion from `Digit` to `byte` is implicit because it never throws exceptions or loses information, but the conversion from `byte` to `Digit` is explicit since `Digit` can only represent a subset of the possible values of a `byte`.

Instance constructors

An *instance constructor* is a member that implements the actions required to initialize an instance of a class. Instance constructors are declared using *constructor_declarations*:

```

constructor_declaration
    : attributes? constructor_modifier* constructor_declarator constructor_body
    ;

constructor_modifier
    : 'public'
    | 'protected'
    | 'internal'
    | 'private'
    | 'extern'
    | constructor_modifier_unsafe
    ;

constructor_declarator
    : identifier '(' formal_parameter_list? ')' constructor_initializer?
    ;

constructor_initializer
    : ':' 'base' '(' argument_list? ')'
    | ':' 'this' '(' argument_list? ')'
    ;

constructor_body
    : block
    | ';'
    ;

```

A *constructor_declaration* may include a set of *attributes* ([Attributes](#)), a valid combination of the four access modifiers ([Access modifiers](#)), and an `extern` ([External methods](#)) modifier. A constructor declaration is not permitted to include the same modifier multiple times.

The *identifier* of a *constructor_declarator* must name the class in which the instance constructor is declared. If

any other name is specified, a compile-time error occurs.

The optional *formal_parameter_list* of an instance constructor is subject to the same rules as the *formal_parameter_list* of a method ([Methods](#)). The formal parameter list defines the signature ([Signatures and overloading](#)) of an instance constructor and governs the process whereby overload resolution ([Type inference](#)) selects a particular instance constructor in an invocation.

Each of the types referenced in the *formal_parameter_list* of an instance constructor must be at least as accessible as the constructor itself ([Accessibility constraints](#)).

The optional *constructor_initializer* specifies another instance constructor to invoke before executing the statements given in the *constructor_body* of this instance constructor. This is described further in [Constructor initializers](#).

When a constructor declaration includes an `extern` modifier, the constructor is said to be an **external constructor**. Because an external constructor declaration provides no actual implementation, its *constructor_body* consists of a semicolon. For all other constructors, the *constructor_body* consists of a *block* which specifies the statements to initialize a new instance of the class. This corresponds exactly to the *block* of an instance method with a `void` return type ([Method body](#)).

Instance constructors are not inherited. Thus, a class has no instance constructors other than those actually declared in the class. If a class contains no instance constructor declarations, a default instance constructor is automatically provided ([Default constructors](#)).

Instance constructors are invoked by *object_creation_expressions* ([Object creation expressions](#)) and through *constructor_initializers*.

Constructor initializers

All instance constructors (except those for class `object`) implicitly include an invocation of another instance constructor immediately before the *constructor_body*. The constructor to implicitly invoke is determined by the *constructor_initializer*.

- An instance constructor initializer of the form `base(argument_list)` or `base()` causes an instance constructor from the direct base class to be invoked. That constructor is selected using *argument_list* if present and the overload resolution rules of [Overload resolution](#). The set of candidate instance constructors consists of all accessible instance constructors contained in the direct base class, or the default constructor ([Default constructors](#)), if no instance constructors are declared in the direct base class. If this set is empty, or if a single best instance constructor cannot be identified, a compile-time error occurs.
- An instance constructor initializer of the form `this(argument-list)` or `this()` causes an instance constructor from the class itself to be invoked. The constructor is selected using *argument_list* if present and the overload resolution rules of [Overload resolution](#). The set of candidate instance constructors consists of all accessible instance constructors declared in the class itself. If this set is empty, or if a single best instance constructor cannot be identified, a compile-time error occurs. If an instance constructor declaration includes a constructor initializer that invokes the constructor itself, a compile-time error occurs.

If an instance constructor has no constructor initializer, a constructor initializer of the form `base()` is implicitly provided. Thus, an instance constructor declaration of the form

```
C(...) {...}
```

is exactly equivalent to

```
C(...): base() {...}
```

The scope of the parameters given by the *formal_parameter_list* of an instance constructor declaration includes

the constructor initializer of that declaration. Thus, a constructor initializer is permitted to access the parameters of the constructor. For example:

```
class A
{
    public A(int x, int y) {}
}

class B: A
{
    public B(int x, int y): base(x + y, x - y) {}
}
```

An instance constructor initializer cannot access the instance being created. Therefore it is a compile-time error to reference `this` in an argument expression of the constructor initializer, as is it a compile-time error for an argument expression to reference any instance member through a *simple_name*.

Instance variable initializers

When an instance constructor has no constructor initializer, or it has a constructor initializer of the form `base(...)`, that constructor implicitly performs the initializations specified by the *variable_initializers* of the instance fields declared in its class. This corresponds to a sequence of assignments that are executed immediately upon entry to the constructor and before the implicit invocation of the direct base class constructor. The variable initializers are executed in the textual order in which they appear in the class declaration.

Constructor execution

Variable initializers are transformed into assignment statements, and these assignment statements are executed before the invocation of the base class instance constructor. This ordering ensures that all instance fields are initialized by their variable initializers before any statements that have access to that instance are executed.

Given the example

```
using System;

class A
{
    public A() {
        PrintFields();
    }

    public virtual void PrintFields() {}
}

class B: A
{
    int x = 1;
    int y;

    public B() {
        y = -1;
    }

    public override void PrintFields() {
        Console.WriteLine("x = {0}, y = {1}", x, y);
    }
}
```

when `new B()` is used to create an instance of `B`, the following output is produced:

```
x = 1, y = 0
```

The value of `x` is 1 because the variable initializer is executed before the base class instance constructor is invoked. However, the value of `y` is 0 (the default value of an `int`) because the assignment to `y` is not executed until after the base class constructor returns.

It is useful to think of instance variable initializers and constructor initializers as statements that are automatically inserted before the *constructor_body*. The example

```
using System;
using System.Collections;

class A
{
    int x = 1, y = -1, count;

    public A() {
        count = 0;
    }

    public A(int n) {
        count = n;
    }
}

class B: A
{
    double sqrt2 = Math.Sqrt(2.0);
    ArrayList items = new ArrayList(100);
    int max;

    public B(): this(100) {
        items.Add("default");
    }

    public B(int n): base(n - 1) {
        max = n;
    }
}
```

contains several variable initializers; it also contains constructor initializers of both forms (`base` and `this`). The example corresponds to the code shown below, where each comment indicates an automatically inserted statement (the syntax used for the automatically inserted constructor invocations isn't valid, but merely serves to illustrate the mechanism).

```

using System.Collections;

class A
{
    int x, y, count;

    public A() {
        x = 1;           // Variable initializer
        y = -1;          // Variable initializer
        object();         // Invoke object() constructor
        count = 0;
    }

    public A(int n) {
        x = 1;           // Variable initializer
        y = -1;          // Variable initializer
        object();         // Invoke object() constructor
        count = n;
    }
}

class B: A
{
    double sqrt2;
    ArrayList items;
    int max;

    public B(): this(100) {
        B(100);          // Invoke B(int) constructor
        items.Add("default");
    }

    public B(int n): base(n - 1) {
        sqrt2 = Math.Sqrt(2.0); // Variable initializer
        items = new ArrayList(100); // Variable initializer
        A(n - 1);             // Invoke A(int) constructor
        max = n;
    }
}

```

Default constructors

If a class contains no instance constructor declarations, a default instance constructor is automatically provided. That default constructor simply invokes the parameterless constructor of the direct base class. If the class is abstract then the declared accessibility for the default constructor is protected. Otherwise, the declared accessibility for the default constructor is public. Thus, the default constructor is always of the form

```
protected C(): base() {}
```

or

```
public C(): base() {}
```

where `C` is the name of the class. If overload resolution is unable to determine a unique best candidate for the base class constructor initializer then a compile-time error occurs.

In the example

```
class Message
{
    object sender;
    string text;
}
```

a default constructor is provided because the class contains no instance constructor declarations. Thus, the example is precisely equivalent to

```
class Message
{
    object sender;
    string text;

    public Message(): base() {}
}
```

Private constructors

When a class `T` declares only private instance constructors, it is not possible for classes outside the program text of `T` to derive from `T` or to directly create instances of `T`. Thus, if a class contains only static members and isn't intended to be instantiated, adding an empty private instance constructor will prevent instantiation. For example:

```
public class Trig
{
    private Trig() {}          // Prevent instantiation

    public const double PI = 3.14159265358979323846;

    public static double Sin(double x) {...}
    public static double Cos(double x) {...}
    public static double Tan(double x) {...}
}
```

The `Trig` class groups related methods and constants, but is not intended to be instantiated. Therefore it declares a single empty private instance constructor. At least one instance constructor must be declared to suppress the automatic generation of a default constructor.

Optional instance constructor parameters

The `this(...)` form of constructor initializer is commonly used in conjunction with overloading to implement optional instance constructor parameters. In the example

```
class Text
{
    public Text(): this(0, 0, null) {}

    public Text(int x, int y): this(x, y, null) {}

    public Text(int x, int y, string s) {
        // Actual constructor implementation
    }
}
```

the first two instance constructors merely provide the default values for the missing arguments. Both use a `this(...)` constructor initializer to invoke the third instance constructor, which actually does the work of initializing the new instance. The effect is that of optional constructor parameters:

```
Text t1 = new Text();           // Same as Text(0, 0, null)
Text t2 = new Text(5, 10);      // Same as Text(5, 10, null)
Text t3 = new Text(5, 20, "Hello");
```

Static constructors

A **static constructor** is a member that implements the actions required to initialize a closed class type. Static constructors are declared using *static_constructor_declarations*:

```
static_constructor_declaration
: attributes? static_constructor_modifiers identifier '(' ' ') static_constructor_body
;

static_constructor_modifiers
: 'extern'? 'static'
| 'static' 'extern'?
| static_constructor_modifiers_unsafe
;

static_constructor_body
: block
| ';'
;
```

A *static_constructor_declaration* may include a set of *attributes* ([Attributes](#)) and an `extern` modifier ([External methods](#)).

The *identifier* of a *static_constructor_declaration* must name the class in which the static constructor is declared. If any other name is specified, a compile-time error occurs.

When a static constructor declaration includes an `extern` modifier, the static constructor is said to be an **external static constructor**. Because an external static constructor declaration provides no actual implementation, its *static_constructor_body* consists of a semicolon. For all other static constructor declarations, the *static_constructor_body* consists of a *block* which specifies the statements to execute in order to initialize the class. This corresponds exactly to the *method_body* of a static method with a `void` return type ([Method body](#)).

Static constructors are not inherited, and cannot be called directly.

The static constructor for a closed class type executes at most once in a given application domain. The execution of a static constructor is triggered by the first of the following events to occur within an application domain:

- An instance of the class type is created.
- Any of the static members of the class type are referenced.

If a class contains the `Main` method ([Application Startup](#)) in which execution begins, the static constructor for that class executes before the `Main` method is called.

To initialize a new closed class type, first a new set of static fields ([Static and instance fields](#)) for that particular closed type is created. Each of the static fields is initialized to its default value ([Default values](#)). Next, the static field initializers ([Static field initialization](#)) are executed for those static fields. Finally, the static constructor is executed.

The example

```

using System;

class Test
{
    static void Main() {
        A.F();
        B.F();
    }
}

class A
{
    static A() {
        Console.WriteLine("Init A");
    }
    public static void F() {
        Console.WriteLine("A.F");
    }
}

class B
{
    static B() {
        Console.WriteLine("Init B");
    }
    public static void F() {
        Console.WriteLine("B.F");
    }
}

```

must produce the output:

```

Init A
A.F
Init B
B.F

```

because the execution of `A`'s static constructor is triggered by the call to `A.F`, and the execution of `B`'s static constructor is triggered by the call to `B.F`.

It is possible to construct circular dependencies that allow static fields with variable initializers to be observed in their default value state.

The example

```

using System;

class A
{
    public static int X;

    static A() {
        X = B.Y + 1;
    }
}

class B
{
    public static int Y = A.X + 1;

    static B() {}

    static void Main() {
        Console.WriteLine("X = {0}, Y = {1}", A.X, B.Y);
    }
}

```

produces the output

```
X = 1, Y = 2
```

To execute the `Main` method, the system first runs the initializer for `B.Y`, prior to class `B`'s static constructor. `Y`'s initializer causes `A`'s static constructor to be run because the value of `A.X` is referenced. The static constructor of `A` in turn proceeds to compute the value of `X`, and in doing so fetches the default value of `Y`, which is zero. `A.X` is thus initialized to 1. The process of running `A`'s static field initializers and static constructor then completes, returning to the calculation of the initial value of `Y`, the result of which becomes 2.

Because the static constructor is executed exactly once for each closed constructed class type, it is a convenient place to enforce run-time checks on the type parameter that cannot be checked at compile-time via constraints ([Type parameter constraints](#)). For example, the following type uses a static constructor to enforce that the type argument is an enum:

```

class Gen<T> where T: struct
{
    static Gen() {
        if (!typeof(T).IsEnum) {
            throw new ArgumentException("T must be an enum");
        }
    }
}

```

Destructors

A **destructor** is a member that implements the actions required to destruct an instance of a class. A destructor is declared using a *destructor_declaration*.

```
destructor_declaration
  : attributes? 'extern'? '~' identifier '(' ' ' ) destructor_body
  | destructor_declaration_unsafe
  ;

destructor_body
  : block
  | ';'
  ;
```

A *destructor_declaration* may include a set of *attributes* ([Attributes](#)).

The *identifier* of a *destructor_declaration* must name the class in which the destructor is declared. If any other name is specified, a compile-time error occurs.

When a destructor declaration includes an `extern` modifier, the destructor is said to be an ***external destructor***. Because an external destructor declaration provides no actual implementation, its *destructor_body* consists of a semicolon. For all other destructors, the *destructor_body* consists of a *block* which specifies the statements to execute in order to destruct an instance of the class. A *destructor_body* corresponds exactly to the *method_body* of an instance method with a `void` return type ([Method body](#)).

Destructors are not inherited. Thus, a class has no destructors other than the one which may be declared in that class.

Since a destructor is required to have no parameters, it cannot be overloaded, so a class can have, at most, one destructor.

Destructors are invoked automatically, and cannot be invoked explicitly. An instance becomes eligible for destruction when it is no longer possible for any code to use that instance. Execution of the destructor for the instance may occur at any time after the instance becomes eligible for destruction. When an instance is destructed, the destructors in that instance's inheritance chain are called, in order, from most derived to least derived. A destructor may be executed on any thread. For further discussion of the rules that govern when and how a destructor is executed, see [Automatic memory management](#).

The output of the example

```

using System;

class A
{
    ~A() {
        Console.WriteLine("A's destructor");
    }
}

class B: A
{
    ~B() {
        Console.WriteLine("B's destructor");
    }
}

class Test
{
    static void Main() {
        B b = new B();
        b = null;
        GC.Collect();
        GC.WaitForPendingFinalizers();
    }
}

```

is

```

B's destructor
A's destructor

```

since destructors in an inheritance chain are called in order, from most derived to least derived.

Destructors are implemented by overriding the virtual method `Finalize` on `System.Object`. C# programs are not permitted to override this method or call it (or overrides of it) directly. For instance, the program

```

class A
{
    override protected void Finalize() {}    // error

    public void F() {
        this.Finalize();                      // error
    }
}

```

contains two errors.

The compiler behaves as if this method, and overrides of it, do not exist at all. Thus, this program:

```

class A
{
    void Finalize() {}                        // permitted
}

```

is valid, and the method shown hides `System.Object`'s `Finalize` method.

For a discussion of the behavior when an exception is thrown from a destructor, see [How exceptions are handled](#).

Iterators

A function member ([Function members](#)) implemented using an iterator block ([Blocks](#)) is called an *iterator*.

An iterator block may be used as the body of a function member as long as the return type of the corresponding function member is one of the enumerator interfaces ([Enumerator interfaces](#)) or one of the enumerable interfaces ([Enumerable interfaces](#)). It can occur as a *method_body*, *operator_body* or *accessor_body*, whereas events, instance constructors, static constructors and destructors cannot be implemented as iterators.

When a function member is implemented using an iterator block, it is a compile-time error for the formal parameter list of the function member to specify any `ref` or `out` parameters.

Enumerator interfaces

The *enumerator interfaces* are the non-generic interface `System.Collections.IEnumerator` and all instantiations of the generic interface `System.Collections.Generic.IEnumerator<T>`. For the sake of brevity, in this chapter these interfaces are referenced as `IEnumerator` and `IEnumerator<T>`, respectively.

Enumerable interfaces

The *enumerable interfaces* are the non-generic interface `System.Collections.IEnumerable` and all instantiations of the generic interface `System.Collections.Generic.IEnumerable<T>`. For the sake of brevity, in this chapter these interfaces are referenced as `IEnumerable` and `IEnumerable<T>`, respectively.

Yield type

An iterator produces a sequence of values, all of the same type. This type is called the *yield type* of the iterator.

- The yield type of an iterator that returns `IEnumerator` or `IEnumerable` is `object`.
- The yield type of an iterator that returns `IEnumerator<T>` or `IEnumerable<T>` is `T`.

Enumerator objects

When a function member returning an enumerator interface type is implemented using an iterator block, invoking the function member does not immediately execute the code in the iterator block. Instead, an *enumerator object* is created and returned. This object encapsulates the code specified in the iterator block, and execution of the code in the iterator block occurs when the enumerator object's `MoveNext` method is invoked. An enumerator object has the following characteristics:

- It implements `IEnumerator` and `IEnumerator<T>`, where `T` is the yield type of the iterator.
- It implements `System.IDisposable`.
- It is initialized with a copy of the argument values (if any) and instance value passed to the function member.
- It has four potential states, *before*, *running*, *suspended*, and *after*, and is initially in the *before* state.

An enumerator object is typically an instance of a compiler-generated enumerator class that encapsulates the code in the iterator block and implements the enumerator interfaces, but other methods of implementation are possible. If an enumerator class is generated by the compiler, that class will be nested, directly or indirectly, in the class containing the function member, it will have private accessibility, and it will have a name reserved for compiler use ([Identifiers](#)).

An enumerator object may implement more interfaces than those specified above.

The following sections describe the exact behavior of the `MoveNext`, `Current`, and `Dispose` members of the `IEnumerable` and `IEnumerable<T>` interface implementations provided by an enumerator object.

Note that enumerator objects do not support the `IEnumerator.Reset` method. Invoking this method causes a `System.NotSupportedException` to be thrown.

The MoveNext method

The `MoveNext` method of an enumerator object encapsulates the code of an iterator block. Invoking the

`MoveNext` method executes code in the iterator block and sets the `Current` property of the enumerator object as appropriate. The precise action performed by `MoveNext` depends on the state of the enumerator object when `MoveNext` is invoked:

- If the state of the enumerator object is *before*, invoking `MoveNext` :
 - Changes the state to *running*.
 - Initializes the parameters (including `this`) of the iterator block to the argument values and instance value saved when the enumerator object was initialized.
 - Executes the iterator block from the beginning until execution is interrupted (as described below).
- If the state of the enumerator object is *running*, the result of invoking `MoveNext` is unspecified.
- If the state of the enumerator object is *suspended*, invoking `MoveNext` :
 - Changes the state to *running*.
 - Restores the values of all local variables and parameters (including `this`) to the values saved when execution of the iterator block was last suspended. Note that the contents of any objects referenced by these variables may have changed since the previous call to `MoveNext`.
 - Resumes execution of the iterator block immediately following the `yield return` statement that caused the suspension of execution and continues until execution is interrupted (as described below).
- If the state of the enumerator object is *after*, invoking `MoveNext` returns `false`.

When `MoveNext` executes the iterator block, execution can be interrupted in four ways: By a `yield return` statement, by a `yield break` statement, by encountering the end of the iterator block, and by an exception being thrown and propagated out of the iterator block.

- When a `yield return` statement is encountered ([The yield statement](#)):
 - The expression given in the statement is evaluated, implicitly converted to the `yield` type, and assigned to the `Current` property of the enumerator object.
 - Execution of the iterator body is suspended. The values of all local variables and parameters (including `this`) are saved, as is the location of this `yield return` statement. If the `yield return` statement is within one or more `try` blocks, the associated `finally` blocks are not executed at this time.
 - The state of the enumerator object is changed to *suspended*.
 - The `MoveNext` method returns `true` to its caller, indicating that the iteration successfully advanced to the next value.
- When a `yield break` statement is encountered ([The yield statement](#)):
 - If the `yield break` statement is within one or more `try` blocks, the associated `finally` blocks are executed.
 - The state of the enumerator object is changed to *after*.
 - The `MoveNext` method returns `false` to its caller, indicating that the iteration is complete.
- When the end of the iterator body is encountered:
 - The state of the enumerator object is changed to *after*.
 - The `MoveNext` method returns `false` to its caller, indicating that the iteration is complete.
- When an exception is thrown and propagated out of the iterator block:
 - Appropriate `finally` blocks in the iterator body will have been executed by the exception propagation.
 - The state of the enumerator object is changed to *after*.
 - The exception propagation continues to the caller of the `MoveNext` method.

The Current property

An enumerator object's `Current` property is affected by `yield return` statements in the iterator block.

When an enumerator object is in the *suspended* state, the value of `Current` is the value set by the previous call

to `MoveNext`. When an enumerator object is in the *before*, *running*, or *after* states, the result of accessing `Current` is unspecified.

For an iterator with a yield type other than `object`, the result of accessing `Current` through the enumerator object's `IEnumerable` implementation corresponds to accessing `Current` through the enumerator object's `IEnumerator<T>` implementation and casting the result to `object`.

The Dispose method

The `Dispose` method is used to clean up the iteration by bringing the enumerator object to the *after* state.

- If the state of the enumerator object is *before*, invoking `Dispose` changes the state to *after*.
- If the state of the enumerator object is *running*, the result of invoking `Dispose` is unspecified.
- If the state of the enumerator object is *suspended*, invoking `Dispose`:
 - Changes the state to *running*.
 - Executes any finally blocks as if the last executed `yield return` statement were a `yield break` statement. If this causes an exception to be thrown and propagated out of the iterator body, the state of the enumerator object is set to *after* and the exception is propagated to the caller of the `Dispose` method.
 - Changes the state to *after*.
- If the state of the enumerator object is *after*, invoking `Dispose` has no effect.

Enumerable objects

When a function member returning an enumerable interface type is implemented using an iterator block, invoking the function member does not immediately execute the code in the iterator block. Instead, an **enumerable object** is created and returned. The enumerable object's `GetEnumerator` method returns an enumerator object that encapsulates the code specified in the iterator block, and execution of the code in the iterator block occurs when the enumerator object's `MoveNext` method is invoked. An enumerable object has the following characteristics:

- It implements `IEnumerable` and `IEnumerator<T>`, where `T` is the yield type of the iterator.
- It is initialized with a copy of the argument values (if any) and instance value passed to the function member.

An enumerable object is typically an instance of a compiler-generated enumerable class that encapsulates the code in the iterator block and implements the enumerable interfaces, but other methods of implementation are possible. If an enumerable class is generated by the compiler, that class will be nested, directly or indirectly, in the class containing the function member, it will have private accessibility, and it will have a name reserved for compiler use ([Identifiers](#)).

An enumerable object may implement more interfaces than those specified above. In particular, an enumerable object may also implement `IEnumerator` and `IEnumerator<T>`, enabling it to serve as both an enumerable and an enumerator. In that type of implementation, the first time an enumerable object's `GetEnumerator` method is invoked, the enumerable object itself is returned. Subsequent invocations of the enumerable object's `GetEnumerator`, if any, return a copy of the enumerable object. Thus, each returned enumerator has its own state and changes in one enumerator will not affect another.

The GetEnumerator method

An enumerable object provides an implementation of the `GetEnumerator` methods of the `IEnumerable` and `IEnumerator<T>` interfaces. The two `GetEnumerator` methods share a common implementation that acquires and returns an available enumerator object. The enumerator object is initialized with the argument values and instance value saved when the enumerable object was initialized, but otherwise the enumerator object functions as described in [Enumerator objects](#).

Implementation example

This section describes a possible implementation of iterators in terms of standard C# constructs. The

implementation described here is based on the same principles used by the Microsoft C# compiler, but it is by no means a mandated implementation or the only one possible.

The following `Stack<T>` class implements its `GetEnumerator` method using an iterator. The iterator enumerates the elements of the stack in top to bottom order.

```
using System;
using System.Collections;
using System.Collections.Generic;

class Stack<T>: IEnumerable<T>
{
    T[] items;
    int count;

    public void Push(T item) {
        if (items == null) {
            items = new T[4];
        }
        else if (items.Length == count) {
            T[] newItems = new T[count * 2];
            Array.Copy(items, 0, newItems, 0, count);
            items = newItems;
        }
        items[count++] = item;
    }

    public T Pop() {
        T result = items[--count];
        items[count] = default(T);
        return result;
    }

    public IEnumerator<T> GetEnumerator() {
        for (int i = count - 1; i >= 0; --i) yield return items[i];
    }
}
```

The `GetEnumerator` method can be translated into an instantiation of a compiler-generated enumerator class that encapsulates the code in the iterator block, as shown in the following.

```

class Stack<T>: IEnumerable<T>
{
    ...

    public IEnumerator<T> GetEnumerator() {
        return new __Enumerator1(this);
    }

    class __Enumerator1: IEnumerator<T>, IEnumerator
    {
        int __state;
        T __current;
        Stack<T> __this;
        int i;

        public __Enumerator1(Stack<T> __this) {
            this.__this = __this;
        }

        public T Current {
            get { return __current; }
        }

        object IEnumerator.Current {
            get { return __current; }
        }

        public bool MoveNext() {
            switch (__state) {
                case 1: goto __state1;
                case 2: goto __state2;
            }
            i = __this.count - 1;
            __loop:
            if (i < 0) goto __state2;
            __current = __this.items[i];
            __state = 1;
            return true;
            __state1:
            --i;
            goto __loop;
            __state2:
            __state = 2;
            return false;
        }

        public void Dispose() {
            __state = 2;
        }

        void IEnumerator.Reset() {
            throw new NotSupportedException();
        }
    }
}

```

In the preceding translation, the code in the iterator block is turned into a state machine and placed in the `MoveNext` method of the enumerator class. Furthermore, the local variable `i` is turned into a field in the enumerator object so it can continue to exist across invocations of `MoveNext`.

The following example prints a simple multiplication table of the integers 1 through 10. The `FromTo` method in the example returns an enumerable object and is implemented using an iterator.

```

using System;
using System.Collections.Generic;

class Test
{
    static IEnumerable<int> FromTo(int from, int to) {
        while (from <= to) yield return from++;
    }

    static void Main() {
        IEnumerable<int> e = FromTo(1, 10);
        foreach (int x in e) {
            foreach (int y in e) {
                Console.Write("{0,3} ", x * y);
            }
            Console.WriteLine();
        }
    }
}

```

The `FromTo` method can be translated into an instantiation of a compiler-generated enumerable class that encapsulates the code in the iterator block, as shown in the following.

```

using System;
using System.Threading;
using System.Collections;
using System.Collections.Generic;

class Test
{
    ...

    static IEnumerable<int> FromTo(int from, int to) {
        return new __Enumerable1(from, to);
    }

    class __Enumerable1:
        IEnumerable<int>, IEnumerable,
        IEnumerator<int>, IEnumerator
    {
        int __state;
        int __current;
        int __from;
        int from;
        int to;
        int i;

        public __Enumerable1(int __from, int to) {
            this.__from = __from;
            this.to = to;
        }

        public IEnumerator<int> GetEnumerator() {
            __Enumerable1 result = this;
            if (Interlocked.CompareExchange(ref __state, 1, 0) != 0) {
                result = new __Enumerable1(__from, to);
                result.__state = 1;
            }
            result.from = result.__from;
            return result;
        }

        IEnumerator IEnumerable.GetEnumerator() {
            return (IEnumerator)GetEnumerator();
        }
    }
}

```

```

    public int Current {
        get { return __current; }
    }

    object IEnumerator.Current {
        get { return __current; }
    }

    public bool MoveNext() {
        switch (__state) {
            case 1:
                if (from > to) goto case 2;
                __current = from++;
                __state = 1;
                return true;
            case 2:
                __state = 2;
                return false;
            default:
                throw new InvalidOperationException();
        }
    }

    public void Dispose() {
        __state = 2;
    }

    void IEnumerator.Reset() {
        throw new NotSupportedException();
    }
}

```

The enumerable class implements both the enumerable interfaces and the enumerator interfaces, enabling it to serve as both an enumerable and an enumerator. The first time the `GetEnumerator` method is invoked, the enumerable object itself is returned. Subsequent invocations of the enumerable object's `GetEnumerator`, if any, return a copy of the enumerable object. Thus, each returned enumerator has its own state and changes in one enumerator will not affect another. The `Interlocked.CompareExchange` method is used to ensure thread-safe operation.

The `from` and `to` parameters are turned into fields in the enumerable class. Because `from` is modified in the iterator block, an additional `__from` field is introduced to hold the initial value given to `from` in each enumerator.

The `MoveNext` method throws an `InvalidOperationException` if it is called when `__state` is `0`. This protects against use of the enumerable object as an enumerator object without first calling `GetEnumerator`.

The following example shows a simple tree class. The `Tree<T>` class implements its `GetEnumerator` method using an iterator. The iterator enumerates the elements of the tree in infix order.

```

using System;
using System.Collections.Generic;

class Tree<T>: IEnumerable<T>
{
    T value;
    Tree<T> left;
    Tree<T> right;

    public Tree(T value, Tree<T> left, Tree<T> right) {
        this.value = value;
        this.left = left;
        this.right = right;
    }

    public IEnumerator<T> GetEnumerator() {
        if (left != null) foreach (T x in left) yield x;
        yield value;
        if (right != null) foreach (T x in right) yield x;
    }
}

class Program
{
    static Tree<T> MakeTree<T>(T[] items, int left, int right) {
        if (left > right) return null;
        int i = (left + right) / 2;
        return new Tree<T>(items[i],
            MakeTree(items, left, i - 1),
            MakeTree(items, i + 1, right));
    }

    static Tree<T> MakeTree<T>(params T[] items) {
        return MakeTree(items, 0, items.Length - 1);
    }

    // The output of the program is:
    // 1 2 3 4 5 6 7 8 9
    // Mon Tue Wed Thu Fri Sat Sun

    static void Main() {
        Tree<int> ints = MakeTree(1, 2, 3, 4, 5, 6, 7, 8, 9);
        foreach (int i in ints) Console.Write("{0} ", i);
        Console.WriteLine();

        Tree<string> strings = MakeTree(
            "Mon", "Tue", "Wed", "Thu", "Fri", "Sat", "Sun");
        foreach (string s in strings) Console.Write("{0} ", s);
        Console.WriteLine();
    }
}

```

The `GetEnumerator` method can be translated into an instantiation of a compiler-generated enumerator class that encapsulates the code in the iterator block, as shown in the following.

```

class Tree<T>: IEnumerable<T>
{
    ...

    public IEnumerator<T> GetEnumerator() {
        return new __Enumerator1(this);
    }

    class __Enumerator1 : IEnumerator<T>, IEnumerator
    {
        Node<T> this:

```

```

Node<T> __this;
IEnumerator<T> __left, __right;
int __state;
T __current;

public __Enumerator1(Node<T> __this) {
    this.__this = __this;
}

public T Current {
    get { return __current; }
}

object IEnumerator.Current {
    get { return __current; }
}

public bool MoveNext() {
    try {
        switch (__state) {

            case 0:
                __state = -1;
                if (__this.left == null) goto __yield_value;
                __left = __this.left.GetEnumerator();
                goto case 1;

            case 1:
                __state = -2;
                if (!__left.MoveNext()) goto __left_dispose;
                __current = __left.Current;
                __state = 1;
                return true;

            __left_dispose:
                __state = -1;
                __left.Dispose();

            __yield_value:
                __current = __this.value;
                __state = 2;
                return true;

            case 2:
                __state = -1;
                if (__this.right == null) goto __end;
                __right = __this.right.GetEnumerator();
                goto case 3;

            case 3:
                __state = -3;
                if (!__right.MoveNext()) goto __right_dispose;
                __current = __right.Current;
                __state = 3;
                return true;

            __right_dispose:
                __state = -1;
                __right.Dispose();

            __end:
                __state = 4;
                break;

        }
    }
    finally {
        if (__state < 0) Dispose();
    }
    return false;
}

```

```

        return false;
    }

    public void Dispose() {
        try {
            switch (__state) {

                case 1:
                case -2:
                    __left.Dispose();
                    break;

                case 3:
                case -3:
                    __right.Dispose();
                    break;

            }
        }
        finally {
            __state = 4;
        }
    }

    void IEnumerator.Reset() {
        throw new NotSupportedException();
    }
}

```

The compiler generated temporaries used in the `foreach` statements are lifted into the `__left` and `__right` fields of the enumerator object. The `__state` field of the enumerator object is carefully updated so that the correct `Dispose()` method will be called correctly if an exception is thrown. Note that it is not possible to write the translated code with simple `foreach` statements.

Async functions

A method ([Methods](#)) or anonymous function ([Anonymous function expressions](#)) with the `async` modifier is called an *async function*. In general, the term *async* is used to describe any kind of function that has the `async` modifier.

It is a compile-time error for the formal parameter list of an async function to specify any `ref` or `out` parameters.

The *return_type* of an async method must be either `void` or a *task type*. The task types are `System.Threading.Tasks.Task` and types constructed from `System.Threading.Tasks.Task<T>`. For the sake of brevity, in this chapter these types are referenced as `Task` and `Task<T>`, respectively. An async method returning a task type is said to be task-returning.

The exact definition of the task types is implementation defined, but from the language's point of view a task type is in one of the states incomplete, succeeded or faulted. A faulted task records a pertinent exception. A succeeded `Task<T>` records a result of type `T`. Task types are awaitable, and can therefore be the operands of await expressions ([Await expressions](#)).

An async function invocation has the ability to suspend evaluation by means of await expressions ([Await expressions](#)) in its body. Evaluation may later be resumed at the point of the suspending await expression by means of a *resumption delegate*. The resumption delegate is of type `System.Action`, and when it is invoked, evaluation of the async function invocation will resume from the await expression where it left off. The *current caller* of an async function invocation is the original caller if the function invocation has never been suspended, or the most recent caller of the resumption delegate otherwise.

Evaluation of a task-returning async function

Invocation of a task-returning async function causes an instance of the returned task type to be generated. This is called the *return task* of the async function. The task is initially in an incomplete state.

The async function body is then evaluated until it is either suspended (by reaching an await expression) or terminates, at which point control is returned to the caller, along with the return task.

When the body of the async function terminates, the return task is moved out of the incomplete state:

- If the function body terminates as the result of reaching a return statement or the end of the body, any result value is recorded in the return task, which is put into a succeeded state.
- If the function body terminates as the result of an uncaught exception ([The throw statement](#)) the exception is recorded in the return task which is put into a faulted state.

Evaluation of a void-returning async function

If the return type of the async function is `void`, evaluation differs from the above in the following way: Because no task is returned, the function instead communicates completion and exceptions to the current thread's *synchronization context*. The exact definition of synchronization context is implementation-dependent, but is a representation of "where" the current thread is running. The synchronization context is notified when evaluation of a void-returning async function commences, completes successfully, or causes an uncaught exception to be thrown.

This allows the context to keep track of how many void-returning async functions are running under it, and to decide how to propagate exceptions coming out of them.

Structs

12/28/2021 • 19 minutes to read • [Edit Online](#)

Structs are similar to classes in that they represent data structures that can contain data members and function members. However, unlike classes, structs are value types and do not require heap allocation. A variable of a struct type directly contains the data of the struct, whereas a variable of a class type contains a reference to the data, the latter known as an object.

Structs are particularly useful for small data structures that have value semantics. Complex numbers, points in a coordinate system, or key-value pairs in a dictionary are all good examples of structs. Key to these data structures is that they have few data members, that they do not require use of inheritance or referential identity, and that they can be conveniently implemented using value semantics where assignment copies the value instead of the reference.

As described in [Simple types](#), the simple types provided by C#, such as `int`, `double`, and `bool`, are in fact all struct types. Just as these predefined types are structs, it is also possible to use structs and operator overloading to implement new "primitive" types in the C# language. Two examples of such types are given at the end of this chapter ([Struct examples](#)).

Struct declarations

A *struct_declaration* is a *type_declaration* ([Type declarations](#)) that declares a new struct:

```
struct_declaration
: attributes? struct_modifier* 'partial'? 'struct' identifier type_parameter_list?
  struct_interfaces? type_parameter_constraints_clause* struct_body ';'?
```

A *struct_declaration* consists of an optional set of *attributes* ([Attributes](#)), followed by an optional set of *struct_modifiers* ([Struct modifiers](#)), followed by an optional `partial` modifier, followed by the keyword `struct` and an *identifier* that names the struct, followed by an optional *type_parameter_list* specification ([Type parameters](#)), followed by an optional *struct_interfaces* specification ([Partial modifier](#)), followed by an optional *type_parameter_constraints_clauses* specification ([Type parameter constraints](#)), followed by a *struct_body* ([Struct body](#)), optionally followed by a semicolon.

Struct modifiers

A *struct_declaration* may optionally include a sequence of struct modifiers:

```
struct_modifier
: 'new'
| 'public'
| 'protected'
| 'internal'
| 'private'
| struct_modifier_unsafe
;
```

It is a compile-time error for the same modifier to appear multiple times in a struct declaration.

The modifiers of a struct declaration have the same meaning as those of a class declaration ([Class declarations](#)).

Partial modifier

The `partial` modifier indicates that this *struct_declaration* is a partial type declaration. Multiple partial struct declarations with the same name within an enclosing namespace or type declaration combine to form one struct declaration, following the rules specified in [Partial types](#).

Struct interfaces

A struct declaration may include a *struct_interfaces* specification, in which case the struct is said to directly implement the given interface types.

```
struct_interfaces
: ':' interface_type_list
;
```

Interface implementations are discussed further in [Interface implementations](#).

Struct body

The *struct_body* of a struct defines the members of the struct.

```
struct_body
: '{' struct_member_declaration* '}'
;
```

Struct members

The members of a struct consist of the members introduced by its *struct_member_declarations* and the members inherited from the type `System.ValueType`.

```
struct_member_declaration
: constant_declaration
| field_declaration
| method_declaration
| property_declaration
| event_declaration
| indexer_declaration
| operator_declaration
| constructor_declaration
| static_constructor_declaration
| type_declaration
| struct_member_declaration_unsafe
;
```

Except for the differences noted in [Class and struct differences](#), the descriptions of class members provided in [Class members](#) through [Async functions](#) apply to struct members as well.

Class and struct differences

Structs differ from classes in several important ways:

- Structs are value types ([Value semantics](#)).
- All struct types implicitly inherit from the class `System.ValueType` ([Inheritance](#)).
- Assignment to a variable of a struct type creates a copy of the value being assigned ([Assignment](#)).
- The default value of a struct is the value produced by setting all value type fields to their default value and all reference type fields to `null` ([Default values](#)).
- Boxing and unboxing operations are used to convert between a struct type and `object` ([Boxing and unboxing](#)).

- The meaning of `this` is different for structs ([This access](#)).
- Instance field declarations for a struct are not permitted to include variable initializers ([Field initializers](#)).
- A struct is not permitted to declare a parameterless instance constructor ([Constructors](#)).
- A struct is not permitted to declare a destructor ([Destructors](#)).

Value semantics

Structs are value types ([Value types](#)) and are said to have value semantics. Classes, on the other hand, are reference types ([Reference types](#)) and are said to have reference semantics.

A variable of a struct type directly contains the data of the struct, whereas a variable of a class type contains a reference to the data, the latter known as an object. When a struct `B` contains an instance field of type `A` and `A` is a struct type, it is a compile-time error for `A` to depend on `B` or a type constructed from `B`. A struct `x` ***directly depends on*** a struct `y` if `x` contains an instance field of type `y`. Given this definition, the complete set of structs upon which a struct depends is the transitive closure of the ***directly depends on*** relationship. For example

```
struct Node
{
    int data;
    Node next; // error, Node directly depends on itself
}
```

is an error because `Node` contains an instance field of its own type. Another example

```
struct A { B b; }

struct B { C c; }

struct C { A a; }
```

is an error because each of the types `A`, `B`, and `C` depend on each other.

With classes, it is possible for two variables to reference the same object, and thus possible for operations on one variable to affect the object referenced by the other variable. With structs, the variables each have their own copy of the data (except in the case of `ref` and `out` parameter variables), and it is not possible for operations on one to affect the other. Furthermore, because structs are not reference types, it is not possible for values of a struct type to be `null`.

Given the declaration

```
struct Point
{
    public int x, y;

    public Point(int x, int y) {
        this.x = x;
        this.y = y;
    }
}
```

the code fragment

```
Point a = new Point(10, 10);
Point b = a;
a.x = 100;
System.Console.WriteLine(b.x);
```

outputs the value `10`. The assignment of `a` to `b` creates a copy of the value, and `b` is thus unaffected by the assignment to `a.x`. Had `Point` instead been declared as a class, the output would be `100` because `a` and `b` would reference the same object.

Inheritance

All struct types implicitly inherit from the class `System.ValueType`, which, in turn, inherits from class `object`. A struct declaration may specify a list of implemented interfaces, but it is not possible for a struct declaration to specify a base class.

Struct types are never abstract and are always implicitly sealed. The `abstract` and `sealed` modifiers are therefore not permitted in a struct declaration.

Since inheritance isn't supported for structs, the declared accessibility of a struct member cannot be `protected` or `protected internal`.

Function members in a struct cannot be `abstract` or `virtual`, and the `override` modifier is allowed only to override methods inherited from `System.ValueType`.

Assignment

Assignment to a variable of a struct type creates a copy of the value being assigned. This differs from assignment to a variable of a class type, which copies the reference but not the object identified by the reference.

Similar to an assignment, when a struct is passed as a value parameter or returned as the result of a function member, a copy of the struct is created. A struct may be passed by reference to a function member using a `ref` or `out` parameter.

When a property or indexer of a struct is the target of an assignment, the instance expression associated with the property or indexer access must be classified as a variable. If the instance expression is classified as a value, a compile-time error occurs. This is described in further detail in [Simple assignment](#).

Default values

As described in [Default values](#), several kinds of variables are automatically initialized to their default value when they are created. For variables of class types and other reference types, this default value is `null`. However, since structs are value types that cannot be `null`, the default value of a struct is the value produced by setting all value type fields to their default value and all reference type fields to `null`.

Referring to the `Point` struct declared above, the example

```
Point[] a = new Point[100];
```

initializes each `Point` in the array to the value produced by setting the `x` and `y` fields to zero.

The default value of a struct corresponds to the value returned by the default constructor of the struct ([Default constructors](#)). Unlike a class, a struct is not permitted to declare a parameterless instance constructor. Instead, every struct implicitly has a parameterless instance constructor which always returns the value that results from setting all value type fields to their default value and all reference type fields to `null`.

Structs should be designed to consider the default initialization state a valid state. In the example

```

using System;

struct KeyValuePair
{
    string key;
    string value;

    public KeyValuePair(string key, string value) {
        if (key == null || value == null) throw new ArgumentException();
        this.key = key;
        this.value = value;
    }
}

```

the user-defined instance constructor protects against null values only where it is explicitly called. In cases where a `KeyValuePair` variable is subject to default value initialization, the `key` and `value` fields will be null, and the struct must be prepared to handle this state.

Boxing and unboxing

A value of a class type can be converted to type `object` or to an interface type that is implemented by the class simply by treating the reference as another type at compile-time. Likewise, a value of type `object` or a value of an interface type can be converted back to a class type without changing the reference (but of course a run-time type check is required in this case).

Since structs are not reference types, these operations are implemented differently for struct types. When a value of a struct type is converted to type `object` or to an interface type that is implemented by the struct, a boxing operation takes place. Likewise, when a value of type `object` or a value of an interface type is converted back to a struct type, an unboxing operation takes place. A key difference from the same operations on class types is that boxing and unboxing copies the struct value either into or out of the boxed instance. Thus, following a boxing or unboxing operation, changes made to the unboxed struct are not reflected in the boxed struct.

When a struct type overrides a virtual method inherited from `System.Object` (such as `Equals`, `GetHashCode`, or `ToString`), invocation of the virtual method through an instance of the struct type does not cause boxing to occur. This is true even when the struct is used as a type parameter and the invocation occurs through an instance of the type parameter type. For example:

```

using System;

struct Counter
{
    int value;

    public override string ToString() {
        value++;
        return value.ToString();
    }
}

class Program
{
    static void Test<T>() where T: new() {
        T x = new T();
        Console.WriteLine(x.ToString());
        Console.WriteLine(x.ToString());
        Console.WriteLine(x.ToString());
    }

    static void Main() {
        Test<Counter>();
    }
}

```

The output of the program is:

```

1
2
3

```

Although it is bad style for `ToString` to have side effects, the example demonstrates that no boxing occurred for the three invocations of `x.ToString()`.

Similarly, boxing never implicitly occurs when accessing a member on a constrained type parameter. For example, suppose an interface `ICounter` contains a method `Increment` which can be used to modify a value. If `ICounter` is used as a constraint, the implementation of the `Increment` method is called with a reference to the variable that `Increment` was called on, never a boxed copy.

```

using System;

interface ICounter
{
    void Increment();
}

struct Counter: ICounter
{
    int value;

    public override string ToString() {
        return value.ToString();
    }

    void ICounter.Increment() {
        value++;
    }
}

class Program
{
    static void Test<T>() where T: ICounter, new() {
        T x = new T();
        Console.WriteLine(x);
        x.Increment();           // Modify x
        Console.WriteLine(x);
        ((ICounter)x).Increment(); // Modify boxed copy of x
        Console.WriteLine(x);
    }

    static void Main() {
        Test<Counter>();
    }
}

```

The first call to `Increment` modifies the value in the variable `x`. This is not equivalent to the second call to `Increment`, which modifies the value in a boxed copy of `x`. Thus, the output of the program is:

```

0
1
1

```

For further details on boxing and unboxing, see [Boxing and unboxing](#).

Meaning of this

Within an instance constructor or instance function member of a class, `this` is classified as a value. Thus, while `this` can be used to refer to the instance for which the function member was invoked, it is not possible to assign to `this` in a function member of a class.

Within an instance constructor of a struct, `this` corresponds to an `out` parameter of the struct type, and within an instance function member of a struct, `this` corresponds to a `ref` parameter of the struct type. In both cases, `this` is classified as a variable, and it is possible to modify the entire struct for which the function member was invoked by assigning to `this` or by passing this as a `ref` or `out` parameter.

Field initializers

As described in [Default values](#), the default value of a struct consists of the value that results from setting all value type fields to their default value and all reference type fields to `null`. For this reason, a struct does not permit instance field declarations to include variable initializers. This restriction applies only to instance fields. Static fields of a struct are permitted to include variable initializers.

The example

```
struct Point
{
    public int x = 1; // Error, initializer not permitted
    public int y = 1; // Error, initializer not permitted
}
```

is in error because the instance field declarations include variable initializers.

Constructors

Unlike a class, a struct is not permitted to declare a parameterless instance constructor. Instead, every struct implicitly has a parameterless instance constructor which always returns the value that results from setting all value type fields to their default value and all reference type fields to null ([Default constructors](#)). A struct can declare instance constructors having parameters. For example

```
struct Point
{
    int x, y;

    public Point(int x, int y) {
        this.x = x;
        this.y = y;
    }
}
```

Given the above declaration, the statements

```
Point p1 = new Point();
Point p2 = new Point(0, 0);
```

both create a `Point` with `x` and `y` initialized to zero.

A struct instance constructor is not permitted to include a constructor initializer of the form `base(...)`.

If the struct instance constructor doesn't specify a constructor initializer, the `this` variable corresponds to an `out` parameter of the struct type, and similar to an `out` parameter, `this` must be definitely assigned ([Definite assignment](#)) at every location where the constructor returns. If the struct instance constructor specifies a constructor initializer, the `this` variable corresponds to a `ref` parameter of the struct type, and similar to a `ref` parameter, `this` is considered definitely assigned on entry to the constructor body. Consider the instance constructor implementation below:

```

struct Point
{
    int x, y;

    public int X {
        set { x = value; }
    }

    public int Y {
        set { y = value; }
    }

    public Point(int x, int y) {
        X = x;          // error, this is not yet definitely assigned
        Y = y;          // error, this is not yet definitely assigned
    }
}

```

No instance member function (including the set accessors for the properties `x` and `y`) can be called until all fields of the struct being constructed have been definitely assigned. The only exception involves automatically implemented properties ([Automatically implemented properties](#)). The definite assignment rules ([Simple assignment expressions](#)) specifically exempt assignment to an auto-property of a struct type within an instance constructor of that struct type: such an assignment is considered a definite assignment of the hidden backing field of the auto-property. Thus, the following is allowed:

```

struct Point
{
    public int X { get; set; }
    public int Y { get; set; }

    public Point(int x, int y) {
        X = x; // allowed, definitely assigns backing field
        Y = y; // allowed, definitely assigns backing field
    }
}

```

Destructors

A struct is not permitted to declare a destructor.

Static constructors

Static constructors for structs follow most of the same rules as for classes. The execution of a static constructor for a struct type is triggered by the first of the following events to occur within an application domain:

- A static member of the struct type is referenced.
- An explicitly declared constructor of the struct type is called.

The creation of default values ([Default values](#)) of struct types does not trigger the static constructor. (An example of this is the initial value of elements in an array.)

Struct examples

The following shows two significant examples of using `struct` types to create types that can be used similarly to the predefined types of the language, but with modified semantics.

Database integer type

The `DBInt` struct below implements an integer type that can represent the complete set of values of the `int` type, plus an additional state that indicates an unknown value. A type with these characteristics is commonly used in databases.

```

using System;

public struct DBInt
{
    // The Null member represents an unknown DBInt value.

    public static readonly DBInt Null = new DBInt();

    // When the defined field is true, this DBInt represents a known value
    // which is stored in the value field. When the defined field is false,
    // this DBInt represents an unknown value, and the value field is 0.

    int value;
    bool defined;

    // Private instance constructor. Creates a DBInt with a known value.

    DBInt(int value) {
        this.value = value;
        this.defined = true;
    }

    // The IsNull property is true if this DBInt represents an unknown value.

    public bool IsNull { get { return !defined; } }

    // The Value property is the known value of this DBInt, or 0 if this
    // DBInt represents an unknown value.

    public int Value { get { return value; } }

    // Implicit conversion from int to DBInt.

    public static implicit operator DBInt(int x) {
        return new DBInt(x);
    }

    // Explicit conversion from DBInt to int. Throws an exception if the
    // given DBInt represents an unknown value.

    public static explicit operator int(DBInt x) {
        if (!x.defined) throw new InvalidOperationException();
        return x.value;
    }

    public static DBInt operator +(DBInt x) {
        return x;
    }

    public static DBInt operator -(DBInt x) {
        return x.defined ? -x.value : Null;
    }

    public static DBInt operator +(DBInt x, DBInt y) {
        return x.defined && y.defined? x.value + y.value: Null;
    }

    public static DBInt operator -(DBInt x, DBInt y) {
        return x.defined && y.defined? x.value - y.value: Null;
    }

    public static DBInt operator *(DBInt x, DBInt y) {
        return x.defined && y.defined? x.value * y.value: Null;
    }

    public static DBInt operator /(DBInt x, DBInt y) {
        return x.defined && y.defined? x.value / y.value: Null;
    }
}

```

```

public static DBInt operator %(DBInt x, DBInt y) {
    return x.defined && y.defined? x.value % y.value: Null;
}

public static DBBool operator ==(DBInt x, DBInt y) {
    return x.defined && y.defined? x.value == y.value: DBBool.Null;
}

public static DBBool operator !=(DBInt x, DBInt y) {
    return x.defined && y.defined? x.value != y.value: DBBool.Null;
}

public static DBBool operator >(DBInt x, DBInt y) {
    return x.defined && y.defined? x.value > y.value: DBBool.Null;
}

public static DBBool operator <(DBInt x, DBInt y) {
    return x.defined && y.defined? x.value < y.value: DBBool.Null;
}

public static DBBool operator >=(DBInt x, DBInt y) {
    return x.defined && y.defined? x.value >= y.value: DBBool.Null;
}

public static DBBool operator <=(DBInt x, DBInt y) {
    return x.defined && y.defined? x.value <= y.value: DBBool.Null;
}

public override bool Equals(object obj) {
    if (!(obj is DBInt)) return false;
    DBInt x = (DBInt)obj;
    return value == x.value && defined == x.defined;
}

public override int GetHashCode() {
    return value;
}

public override string ToString() {
    return defined? value.ToString(): "DBInt.Null";
}
}

```

Database boolean type

The `DBBool` struct below implements a three-valued logical type. The possible values of this type are `DBBool.True`, `DBBool.False`, and `DBBool.Null`, where the `Null` member indicates an unknown value. Such three-valued logical types are commonly used in databases.

```

using System;

public struct DBBool
{
    // The three possible DBBool values.

    public static readonly DBBool Null = new DBBool(0);
    public static readonly DBBool False = new DBBool(-1);
    public static readonly DBBool True = new DBBool(1);

    // Private field that stores -1, 0, 1 for False, Null, True.

    sbyte value;

    // Private instance constructor. The value parameter must be -1, 0, or 1.

    DBBool(int value) {

```

```

        this.value = (sbyte)value;
    }

    // Properties to examine the value of a DBBool. Return true if this
    // DBBool has the given value, false otherwise.

    public bool IsNull { get { return value == 0; } }

    public bool IsFalse { get { return value < 0; } }

    public bool IsTrue { get { return value > 0; } }

    // Implicit conversion from bool to DBBool. Maps true to DBBool.True and
    // false to DBBool.False.

    public static implicit operator DBBool(bool x) {
        return x? True: False;
    }

    // Explicit conversion from DBBool to bool. Throws an exception if the
    // given DBBool is Null, otherwise returns true or false.

    public static explicit operator bool(DBBool x) {
        if (x.value == 0) throw new InvalidOperationException();
        return x.value > 0;
    }

    // Equality operator. Returns Null if either operand is Null, otherwise
    // returns True or False.

    public static DBBool operator ==(DBBool x, DBBool y) {
        if (x.value == 0 || y.value == 0) return Null;
        return x.value == y.value? True: False;
    }

    // Inequality operator. Returns Null if either operand is Null, otherwise
    // returns True or False.

    public static DBBool operator !=(DBBool x, DBBool y) {
        if (x.value == 0 || y.value == 0) return Null;
        return x.value != y.value? True: False;
    }

    // Logical negation operator. Returns True if the operand is False, Null
    // if the operand is Null, or False if the operand is True.

    public static DBBool operator !(DBBool x) {
        return new DBBool(-x.value);
    }

    // Logical AND operator. Returns False if either operand is False,
    // otherwise Null if either operand is Null, otherwise True.

    public static DBBool operator &(DBBool x, DBBool y) {
        return new DBBool(x.value < y.value? x.value: y.value);
    }

    // Logical OR operator. Returns True if either operand is True, otherwise
    // Null if either operand is Null, otherwise False.

    public static DBBool operator |(DBBool x, DBBool y) {
        return new DBBool(x.value > y.value? x.value: y.value);
    }

    // Definitely true operator. Returns true if the operand is True, false
    // otherwise.

    public static bool operator true(DBBool x) {
        return x.value > 0;
    }

```

```
        return x.value < 0;
    }

    // Definitely false operator. Returns true if the operand is False, false
    // otherwise.

    public static bool operator false(DBBool x) {
        return x.value < 0;
    }

    public override bool Equals(object obj) {
        if (!(obj is DBBool)) return false;
        return value == ((DBBool)obj).value;
    }

    public override int GetHashCode() {
        return value;
    }

    public override string ToString() {
        if (value > 0) return "DBBool.True";
        if (value < 0) return "DBBool.False";
        return "DBBool.Null";
    }
}
```

Arrays

12/28/2021 • 9 minutes to read • [Edit Online](#)

An array is a data structure that contains a number of variables which are accessed through computed indices. The variables contained in an array, also called the elements of the array, are all of the same type, and this type is called the element type of the array.

An array has a rank which determines the number of indices associated with each array element. The rank of an array is also referred to as the dimensions of the array. An array with a rank of one is called a *single-dimensional array*. An array with a rank greater than one is called a *multi-dimensional array*. Specific sized multi-dimensional arrays are often referred to as two-dimensional arrays, three-dimensional arrays, and so on.

Each dimension of an array has an associated length which is an integral number greater than or equal to zero. The dimension lengths are not part of the type of the array, but rather are established when an instance of the array type is created at run-time. The length of a dimension determines the valid range of indices for that dimension: For a dimension of length `N`, indices can range from `0` to `N - 1` inclusive. The total number of elements in an array is the product of the lengths of each dimension in the array. If one or more of the dimensions of an array have a length of zero, the array is said to be empty.

The element type of an array can be any type, including an array type.

Array types

An array type is written as a *non_array_type* followed by one or more *rank_specifiers*:

```
array_type
: non_array_type rank_specifier+
;

non_array_type
: type
;

rank_specifier
: '[' dim_separator* '['
;

dim_separator
: ','
;
```

A *non_array_type* is any *type* that is not itself an *array_type*.

The rank of an array type is given by the leftmost *rank_specifier* in the *array_type*. A *rank_specifier* indicates that the array is an array with a rank of one plus the number of "`[`", "`,`" tokens in the *rank_specifier*.

The element type of an array type is the type that results from deleting the leftmost *rank_specifier*:

- An array type of the form `T[R]` is an array with rank `R` and a non-array element type `T`.
- An array type of the form `T[R][R1]...[Rn]` is an array with rank `R` and an element type `T[R1]...[Rn]`.

In effect, the *rank_specifiers* are read from left to right before the final non-array element type. The type `int[][,][,]` is a single-dimensional array of three-dimensional arrays of two-dimensional arrays of `int`.

At run-time, a value of an array type can be `null` or a reference to an instance of that array type.

The System.Array type

The type `System.Array` is the abstract base type of all array types. An implicit reference conversion ([Implicit reference conversions](#)) exists from any array type to `System.Array`, and an explicit reference conversion ([Explicit reference conversions](#)) exists from `System.Array` to any array type. Note that `System.Array` is not itself an *array_type*. Rather, it is a *class_type* from which all *array_types* are derived.

At run-time, a value of type `System.Array` can be `null` or a reference to an instance of any array type.

Arrays and the generic IList interface

A one-dimensional array `T[]` implements the interface `System.Collections.Generic.IList<T>` (`IList<T>` for short) and its base interfaces. Accordingly, there is an implicit conversion from `T[]` to `IList<T>` and its base interfaces. In addition, if there is an implicit reference conversion from `S` to `T` then `S[]` implements `IList<T>` and there is an implicit reference conversion from `S[]` to `IList<T>` and its base interfaces ([Implicit reference conversions](#)). If there is an explicit reference conversion from `S` to `T` then there is an explicit reference conversion from `S[]` to `IList<T>` and its base interfaces ([Explicit reference conversions](#)). For example:

```
using System.Collections.Generic;

class Test
{
    static void Main() {
        string[] sa = new string[5];
        object[] oa1 = new object[5];
        object[] oa2 = sa;

        IList<string> lst1 = sa;           // Ok
        IList<string> lst2 = oa1;          // Error, cast needed
        IList<object> lst3 = sa;           // Ok
        IList<object> lst4 = oa1;          // Ok

        IList<string> lst5 = (IList<string>)oa1; // Exception
        IList<string> lst6 = (IList<string>)oa2; // Ok
    }
}
```

The assignment `lst2 = oa1` generates a compile-time error since the conversion from `object[]` to `IList<string>` is an explicit conversion, not implicit. The cast `(IList<string>)oa1` will cause an exception to be thrown at run-time since `oa1` references an `object[]` and not a `string[]`. However the cast `(IList<string>)oa2` will not cause an exception to be thrown since `oa2` references a `string[]`.

Whenever there is an implicit or explicit reference conversion from `S[]` to `IList<T>`, there is also an explicit reference conversion from `IList<T>` and its base interfaces to `S[]` ([Explicit reference conversions](#)).

When an array type `S[]` implements `IList<T>`, some of the members of the implemented interface may throw exceptions. The precise behavior of the implementation of the interface is beyond the scope of this specification.

Array creation

Array instances are created by *array_creation_expressions* ([Array creation expressions](#)) or by field or local variable declarations that include an *array_initializer* ([Array initializers](#)).

When an array instance is created, the rank and length of each dimension are established and then remain constant for the entire lifetime of the instance. In other words, it is not possible to change the rank of an existing array instance, nor is it possible to resize its dimensions.

An array instance is always of an array type. The `System.Array` type is an abstract type that cannot be

instantiated.

Elements of arrays created by *array_creation_expressions* are always initialized to their default value ([Default values](#)).

Array element access

Array elements are accessed using *element_access* expressions ([Array access](#)) of the form `A[I1, I2, ..., In]`, where `A` is an expression of an array type and each `Ix` is an expression of type `int`, `uint`, `long`, `ulong`, or can be implicitly converted to one or more of these types. The result of an array element access is a variable, namely the array element selected by the indices.

The elements of an array can be enumerated using a `foreach` statement ([The foreach statement](#)).

Array members

Every array type inherits the members declared by the `System.Array` type.

Array covariance

For any two *reference_types* `A` and `B`, if an implicit reference conversion ([Implicit reference conversions](#)) or explicit reference conversion ([Explicit reference conversions](#)) exists from `A` to `B`, then the same reference conversion also exists from the array type `A[R]` to the array type `B[R]`, where `R` is any given *rank_specifier* (but the same for both array types). This relationship is known as **array covariance**. Array covariance in particular means that a value of an array type `A[R]` may actually be a reference to an instance of an array type `B[R]`, provided an implicit reference conversion exists from `B` to `A`.

Because of array covariance, assignments to elements of reference type arrays include a run-time check which ensures that the value being assigned to the array element is actually of a permitted type ([Simple assignment](#)). For example:

```
class Test
{
    static void Fill(object[] array, int index, int count, object value) {
        for (int i = index; i < index + count; i++) array[i] = value;
    }

    static void Main() {
        string[] strings = new string[100];
        Fill(strings, 0, 100, "Undefined");
        Fill(strings, 0, 10, null);
        Fill(strings, 90, 10, 0);
    }
}
```

The assignment to `array[i]` in the `Fill` method implicitly includes a run-time check which ensures that the object referenced by `value` is either `null` or an instance that is compatible with the actual element type of `array`. In `Main`, the first two invocations of `Fill` succeed, but the third invocation causes a `System.ArrayTypeMismatchException` to be thrown upon executing the first assignment to `array[i]`. The exception occurs because a boxed `int` cannot be stored in a `string` array.

Array covariance specifically does not extend to arrays of *value_types*. For example, no conversion exists that permits an `int[]` to be treated as an `object[]`.

Array initializers

Array initializers may be specified in field declarations ([Fields](#)), local variable declarations ([Local variable declarations](#)), and array creation expressions ([Array creation expressions](#)):

```
array_initializer
    : '{' variable_initializer_list? '}'
    | '{' variable_initializer_list ',' '}'
    ;

variable_initializer_list
    : variable_initializer (',' variable_initializer)*
    ;

variable_initializer
    : expression
    | array_initializer
    ;
```

An array initializer consists of a sequence of variable initializers, enclosed by "{" and "}" tokens and separated by "," tokens. Each variable initializer is an expression or, in the case of a multi-dimensional array, a nested array initializer.

The context in which an array initializer is used determines the type of the array being initialized. In an array creation expression, the array type immediately precedes the initializer, or is inferred from the expressions in the array initializer. In a field or variable declaration, the array type is the type of the field or variable being declared. When an array initializer is used in a field or variable declaration, such as:

```
int[] a = {0, 2, 4, 6, 8};
```

it is simply shorthand for an equivalent array creation expression:

```
int[] a = new int[] {0, 2, 4, 6, 8};
```

For a single-dimensional array, the array initializer must consist of a sequence of expressions that are assignment compatible with the element type of the array. The expressions initialize array elements in increasing order, starting with the element at index zero. The number of expressions in the array initializer determines the length of the array instance being created. For example, the array initializer above creates an `int[]` instance of length 5 and then initializes the instance with the following values:

```
a[0] = 0; a[1] = 2; a[2] = 4; a[3] = 6; a[4] = 8;
```

For a multi-dimensional array, the array initializer must have as many levels of nesting as there are dimensions in the array. The outermost nesting level corresponds to the leftmost dimension and the innermost nesting level corresponds to the rightmost dimension. The length of each dimension of the array is determined by the number of elements at the corresponding nesting level in the array initializer. For each nested array initializer, the number of elements must be the same as the other array initializers at the same level. The example:

```
int[,] b = {{0, 1}, {2, 3}, {4, 5}, {6, 7}, {8, 9}};
```

creates a two-dimensional array with a length of five for the leftmost dimension and a length of two for the rightmost dimension:

```
int[,] b = new int[5, 2];
```

and then initializes the array instance with the following values:

```
b[0, 0] = 0; b[0, 1] = 1;  
b[1, 0] = 2; b[1, 1] = 3;  
b[2, 0] = 4; b[2, 1] = 5;  
b[3, 0] = 6; b[3, 1] = 7;  
b[4, 0] = 8; b[4, 1] = 9;
```

If a dimension other than the rightmost is given with length zero, the subsequent dimensions are assumed to also have length zero. The example:

```
int[, ] c = {};
```

creates a two-dimensional array with a length of zero for both the leftmost and the rightmost dimension:

```
int[, ] c = new int[0, 0];
```

When an array creation expression includes both explicit dimension lengths and an array initializer, the lengths must be constant expressions and the number of elements at each nesting level must match the corresponding dimension length. Here are some examples:

```
int i = 3;  
int[] x = new int[3] {0, 1, 2};           // OK  
int[] y = new int[i] {0, 1, 2};           // Error, i not a constant  
int[] z = new int[3] {0, 1, 2, 3};         // Error, length/initializer mismatch
```

Here, the initializer for `y` results in a compile-time error because the dimension length expression is not a constant, and the initializer for `z` results in a compile-time error because the length and the number of elements in the initializer do not agree.

Interfaces

12/28/2021 • 29 minutes to read • [Edit Online](#)

An interface defines a contract. A class or struct that implements an interface must adhere to its contract. An interface may inherit from multiple base interfaces, and a class or struct may implement multiple interfaces.

Interfaces can contain methods, properties, events, and indexers. The interface itself does not provide implementations for the members that it defines. The interface merely specifies the members that must be supplied by classes or structs that implement the interface.

Interface declarations

An *interface_declaration* is a *type_declaration* ([Type declarations](#)) that declares a new interface type.

```
interface_declaration
: attributes? interface_modifier* 'partial'? 'interface'
  identifier variant_type_parameter_list? interface_base?
  type_parameter_constraints_clause* interface_body ';'?
```

An *interface_declaration* consists of an optional set of *attributes* ([Attributes](#)), followed by an optional set of *interface_modifiers* ([Interface modifiers](#)), followed by an optional `partial` modifier, followed by the keyword `interface` and an *identifier* that names the interface, followed by an optional *variant_type_parameter_list* specification ([Variant type parameter lists](#)), followed by an optional *interface_base* specification ([Base interfaces](#)), followed by an optional *type_parameter_constraints_clauses* specification ([Type parameter constraints](#)), followed by an *interface_body* ([Interface body](#)), optionally followed by a semicolon.

Interface modifiers

An *interface_declaration* may optionally include a sequence of interface modifiers:

```
interface_modifier
: 'new'
| 'public'
| 'protected'
| 'internal'
| 'private'
| interface_modifier_unsafe
```

It is a compile-time error for the same modifier to appear multiple times in an interface declaration.

The `new` modifier is only permitted on interfaces defined within a class. It specifies that the interface hides an inherited member by the same name, as described in [The new modifier](#).

The `public`, `protected`, `internal`, and `private` modifiers control the accessibility of the interface. Depending on the context in which the interface declaration occurs, only some of these modifiers may be permitted ([Declared accessibility](#)).

Partial modifier

The `partial` modifier indicates that this *interface_declaration* is a partial type declaration. Multiple partial interface declarations with the same name within an enclosing namespace or type declaration combine to form one interface declaration, following the rules specified in [Partial types](#).

Variant type parameter lists

Variant type parameter lists can only occur on interface and delegate types. The difference from ordinary *type_parameter_lists* is the optional *variance_annotation* on each type parameter.

```
variant_type_parameter_list
: '<' variant_type_parameters '>'
;

variant_type_parameters
: attributes? variance_annotation? type_parameter
| variant_type_parameters ',' attributes? variance_annotation? type_parameter
;

variance_annotation
: 'in'
| 'out'
;
```

If the variance annotation is `out`, the type parameter is said to be *covariant*. If the variance annotation is `in`, the type parameter is said to be *contravariant*. If there is no variance annotation, the type parameter is said to be *invariant*.

In the example

```
interface C<out X, in Y, Z>
{
    X M(Y y);
    Z P { get; set; }
}
```

`X` is covariant, `Y` is contravariant and `Z` is invariant.

Variance safety

The occurrence of variance annotations in the type parameter list of a type restricts the places where types can occur within the type declaration.

A type `T` is *output-unsafe* if one of the following holds:

- `T` is a contravariant type parameter
- `T` is an array type with an output-unsafe element type
- `T` is an interface or delegate type `S<A1, ..., Ak>` constructed from a generic type `S<X1, ..., Xk>` where for at least one `Ai` one of the following holds:
 - `Xi` is covariant or invariant and `Ai` is output-unsafe.
 - `Xi` is contravariant or invariant and `Ai` is input-safe.

A type `T` is *input-unsafe* if one of the following holds:

- `T` is a covariant type parameter
- `T` is an array type with an input-unsafe element type
- `T` is an interface or delegate type `S<A1, ..., Ak>` constructed from a generic type `S<X1, ..., Xk>` where for at least one `Ai` one of the following holds:
 - `Xi` is covariant or invariant and `Ai` is input-unsafe.
 - `Xi` is contravariant or invariant and `Ai` is output-unsafe.

Intuitively, an output-unsafe type is prohibited in an output position, and an input-unsafe type is prohibited in an input position.

A type is *output-safe* if it is not output-unsafe, and *input-safe* if it is not input-unsafe.

Variance conversion

The purpose of variance annotations is to provide for more lenient (but still type safe) conversions to interface and delegate types. To this end the definitions of implicit ([Implicit conversions](#)) and explicit conversions ([Explicit conversions](#)) make use of the notion of variance-convertibility, which is defined as follows:

A type $T\langle A_1, \dots, A_n \rangle$ is variance-convertible to a type $T\langle B_1, \dots, B_n \rangle$ if T is either an interface or a delegate type declared with the variant type parameters $T\langle X_1, \dots, X_n \rangle$, and for each variant type parameter X_i one of the following holds:

- X_i is covariant and an implicit reference or identity conversion exists from A_i to B_i
- X_i is contravariant and an implicit reference or identity conversion exists from B_i to A_i
- X_i is invariant and an identity conversion exists from A_i to B_i

Base interfaces

An interface can inherit from zero or more interface types, which are called the *explicit base interfaces* of the interface. When an interface has one or more explicit base interfaces, then in the declaration of that interface, the interface identifier is followed by a colon and a comma separated list of base interface types.

```
interface_base
: ':' interface_type_list
;
```

For a constructed interface type, the explicit base interfaces are formed by taking the explicit base interface declarations on the generic type declaration, and substituting, for each *type_parameter* in the base interface declaration, the corresponding *type_argument* of the constructed type.

The explicit base interfaces of an interface must be at least as accessible as the interface itself ([Accessibility constraints](#)). For example, it is a compile-time error to specify a `private` or `internal` interface in the *interface_base* of a `public` interface.

It is a compile-time error for an interface to directly or indirectly inherit from itself.

The *base interfaces* of an interface are the explicit base interfaces and their base interfaces. In other words, the set of base interfaces is the complete transitive closure of the explicit base interfaces, their explicit base interfaces, and so on. An interface inherits all members of its base interfaces. In the example

```
interface IControl
{
    void Paint();
}

interface ITextBox: IControl
{
    void SetText(string text);
}

interface IListBox: IControl
{
    void SetItems(string[] items);
}

interface IComboBox: ITextBox, IListBox {}
```

the base interfaces of `IComboBox` are `IControl`, `ITextBox`, and `IListBox`.

In other words, the `IComboBox` interface above inherits members `SetText` and `SetItems` as well as `Paint`.

Every base interface of an interface must be output-safe ([Variance safety](#)). A class or struct that implements an interface also implicitly implements all of the interface's base interfaces.

Interface body

The *interface_body* of an interface defines the members of the interface.

```
interface_body
: '{' interface_member_declaration* '}'
;
```

Interface members

The members of an interface are the members inherited from the base interfaces and the members declared by the interface itself.

```
interface_member_declaration
: interface_method_declaration
| interface_property_declaration
| interface_event_declaration
| interface_indexer_declaration
;
```

An interface declaration may declare zero or more members. The members of an interface must be methods, properties, events, or indexers. An interface cannot contain constants, fields, operators, instance constructors, destructors, or types, nor can an interface contain static members of any kind.

All interface members implicitly have public access. It is a compile-time error for interface member declarations to include any modifiers. In particular, interfaces members cannot be declared with the modifiers `abstract`, `public`, `protected`, `internal`, `private`, `virtual`, `override`, or `static`.

The example

```
public delegate void StringListEvent(IStringList sender);

public interface IStringList
{
    void Add(string s);
    int Count { get; }
    event StringListEvent Changed;
    string this[int index] { get; set; }
}
```

declares an interface that contains one each of the possible kinds of members: A method, a property, an event, and an indexer.

An *interface_declaration* creates a new declaration space ([Declarations](#)), and the *interface_member_declarations* immediately contained by the *interface_declaration* introduce new members into this declaration space. The following rules apply to *interface_member_declarations*:

- The name of a method must differ from the names of all properties and events declared in the same interface. In addition, the signature ([Signatures and overloading](#)) of a method must differ from the signatures of all other methods declared in the same interface, and two methods declared in the same interface may not have signatures that differ solely by `ref` and `out`.
- The name of a property or event must differ from the names of all other members declared in the same interface.
- The signature of an indexer must differ from the signatures of all other indexers declared in the same

interface.

The inherited members of an interface are specifically not part of the declaration space of the interface. Thus, an interface is allowed to declare a member with the same name or signature as an inherited member. When this occurs, the derived interface member is said to hide the base interface member. Hiding an inherited member is not considered an error, but it does cause the compiler to issue a warning. To suppress the warning, the declaration of the derived interface member must include a `new` modifier to indicate that the derived member is intended to hide the base member. This topic is discussed further in [Hiding through inheritance](#).

If a `new` modifier is included in a declaration that doesn't hide an inherited member, a warning is issued to that effect. This warning is suppressed by removing the `new` modifier.

Note that the members in class `object` are not, strictly speaking, members of any interface ([Interface members](#)). However, the members in class `object` are available via member lookup in any interface type ([Member lookup](#)).

Interface methods

Interface methods are declared using *interface_method_declarations*:

```
interface_method_declaration
: attributes? 'new'? return_type identifier type_parameter_list
  '(' formal_parameter_list? ')' type_parameter_constraints_clause* ';'
;
```

The *attributes*, *return_type*, *identifier*, and *formal_parameter_list* of an interface method declaration have the same meaning as those of a method declaration in a class ([Methods](#)). An interface method declaration is not permitted to specify a method body, and the declaration therefore always ends with a semicolon.

Each formal parameter type of an interface method must be input-safe ([Variance safety](#)), and the return type must be either `void` or output-safe. Furthermore, each class type constraint, interface type constraint and type parameter constraint on any type parameter of the method must be input-safe.

These rules ensure that any covariant or contravariant usage of the interface remains type-safe. For example,

```
interface I<out T> { void M<U>() where U : T; }
```

is illegal because the usage of `T` as a type parameter constraint on `U` is not input-safe.

Were this restriction not in place it would be possible to violate type safety in the following manner:

```
class B {}
class D : B {}
class E : B {}
class C : I<D> { public void M<U>() {...} }
...
I<B> b = new C();
b.M<E>();
```

This is actually a call to `C.M<E>`. But that call requires that `E` derive from `D`, so type safety would be violated here.

Interface properties

Interface properties are declared using *interface_property_declarations*:

```

interface_property_declaration
: attributes? 'new'? type identifier '{' interface_accessors '}'
;

interface_accessors
: attributes? 'get' ';'
| attributes? 'set' ';'
| attributes? 'get' ';' attributes? 'set' ';'
| attributes? 'set' ';' attributes? 'get' ';'
;

```

The *attributes*, *type*, and *identifier* of an interface property declaration have the same meaning as those of a property declaration in a class ([Properties](#)).

The accessors of an interface property declaration correspond to the accessors of a class property declaration ([Accessors](#)), except that the accessor body must always be a semicolon. Thus, the accessors simply indicate whether the property is read-write, read-only, or write-only.

The type of an interface property must be output-safe if there is a get accessor, and must be input-safe if there is a set accessor.

Interface events

Interface events are declared using *interface_event_declarations*:

```

interface_event_declaration
: attributes? 'new'? 'event' type identifier ';'
;

```

The *attributes*, *type*, and *identifier* of an interface event declaration have the same meaning as those of an event declaration in a class ([Events](#)).

The type of an interface event must be input-safe.

Interface indexers

Interface indexers are declared using *interface_indexer_declarations*:

```

interface_indexer_declaration
: attributes? 'new'? type 'this' '[' formal_parameter_list ']' '{' interface_accessors '}'
;

```

The *attributes*, *type*, and *formal_parameter_list* of an interface indexer declaration have the same meaning as those of an indexer declaration in a class ([Indexers](#)).

The accessors of an interface indexer declaration correspond to the accessors of a class indexer declaration ([Indexers](#)), except that the accessor body must always be a semicolon. Thus, the accessors simply indicate whether the indexer is read-write, read-only, or write-only.

All the formal parameter types of an interface indexer must be input-safe. In addition, any `out` or `ref` formal parameter types must also be output-safe. Note that even `out` parameters are required to be input-safe, due to a limitation of the underlying execution platform.

The type of an interface indexer must be output-safe if there is a get accessor, and must be input-safe if there is a set accessor.

Interface member access

Interface members are accessed through member access ([Member access](#)) and indexer access ([Indexer access](#)) expressions of the form `I.M` and `I[A]`, where `I` is an interface type, `M` is a method, property, or event of that

interface type, and `A` is an indexer argument list.

For interfaces that are strictly single-inheritance (each interface in the inheritance chain has exactly zero or one direct base interface), the effects of the member lookup ([Member lookup](#)), method invocation ([Method invocations](#)), and indexer access ([Indexer access](#)) rules are exactly the same as for classes and structs: More derived members hide less derived members with the same name or signature. However, for multiple-inheritance interfaces, ambiguities can occur when two or more unrelated base interfaces declare members with the same name or signature. This section shows several examples of such situations. In all cases, explicit casts can be used to resolve the ambiguities.

In the example

```
interface IList
{
    int Count { get; set; }
}

interface ICounter
{
    void Count(int i);
}

interface IListCounter: IList, ICounter {}

class C
{
    void Test(IListCounter x) {
        x.Count(1);           // Error
        x.Count = 1;          // Error
        ((IList)x).Count = 1; // Ok, invokes IList.Count.set
        ((ICounter)x).Count(1); // Ok, invokes ICounter.Count
    }
}
```

the first two statements cause compile-time errors because the member lookup ([Member lookup](#)) of `Count` in `IListCounter` is ambiguous. As illustrated by the example, the ambiguity is resolved by casting `x` to the appropriate base interface type. Such casts have no run-time costs—they merely consist of viewing the instance as a less derived type at compile-time.

In the example

```

interface IInteger
{
    void Add(int i);
}

interface IDouble
{
    void Add(double d);
}

interface INumber: IInteger, IDouble {}

class C
{
    void Test(INumber n) {
        n.Add(1);           // Invokes IInteger.Add
        n.Add(1.0);         // Only IDouble.Add is applicable
        ((IInteger)n).Add(1); // Only IInteger.Add is a candidate
        ((IDouble)n).Add(1);  // Only IDouble.Add is a candidate
    }
}

```

the invocation `n.Add(1)` selects `IInteger.Add` by applying the overload resolution rules of [Overload resolution](#). Similarly the invocation `n.Add(1.0)` selects `IDouble.Add`. When explicit casts are inserted, there is only one candidate method, and thus no ambiguity.

In the example

```

interface IBase
{
    void F(int i);
}

interface ILeft: IBase
{
    new void F(int i);
}

interface IRight: IBase
{
    void G();
}

interface IDerived: ILeft, IRight {}

class A
{
    void Test(IDerived d) {
        d.F(1);           // Invokes ILeft.F
        ((IBase)d).F(1);   // Invokes IBase.F
        ((ILeft)d).F(1);   // Invokes ILeft.F
        ((IRight)d).F(1);  // Invokes IBase.F
    }
}

```

the `IBase.F` member is hidden by the `ILeft.F` member. The invocation `d.F(1)` thus selects `ILeft.F`, even though `IBase.F` appears to not be hidden in the access path that leads through `IRight`.

The intuitive rule for hiding in multiple-inheritance interfaces is simply this: If a member is hidden in any access path, it is hidden in all access paths. Because the access path from `IDerived` to `ILeft` to `IBase` hides `IBase.F`, the member is also hidden in the access path from `IDerived` to `IRight` to `IBase`.

Fully qualified interface member names

An interface member is sometimes referred to by its *fully qualified name*. The fully qualified name of an interface member consists of the name of the interface in which the member is declared, followed by a dot, followed by the name of the member. The fully qualified name of a member references the interface in which the member is declared. For example, given the declarations

```
interface IControl
{
    void Paint();
}

interface ITextBox: IControl
{
    void SetText(string text);
}
```

the fully qualified name of `Paint` is `IControl.Paint` and the fully qualified name of `SetText` is `ITextBox.SetText`.

In the example above, it is not possible to refer to `Paint` as `ITextBox.Paint`.

When an interface is part of a namespace, the fully qualified name of an interface member includes the namespace name. For example

```
namespace System
{
    public interface ICloneable
    {
        object Clone();
    }
}
```

Here, the fully qualified name of the `Clone` method is `System.ICloneable.Clone`.

Interface implementations

Interfaces may be implemented by classes and structs. To indicate that a class or struct directly implements an interface, the interface identifier is included in the base class list of the class or struct. For example:

```
interface ICloneable
{
    object Clone();
}

interface IComparable
{
    int CompareTo(object other);
}

class ListEntry: ICloneable, IComparable
{
    public object Clone() {...}
    public int CompareTo(object other) {...}
}
```

A class or struct that directly implements an interface also directly implements all of the interface's base interfaces implicitly. This is true even if the class or struct doesn't explicitly list all base interfaces in the base class list. For example:

```

interface IControl
{
    void Paint();
}

interface ITextBox: IControl
{
    void SetText(string text);
}

class TextBox: ITextBox
{
    public void Paint() {...}
    public void SetText(string text) {...}
}

```

Here, class `TextBox` implements both `IControl` and `ITextBox`.

When a class `C` directly implements an interface, all classes derived from `C` also implement the interface implicitly. The base interfaces specified in a class declaration can be constructed interface types ([Constructed types](#)). A base interface cannot be a type parameter on its own, though it can involve the type parameters that are in scope. The following code illustrates how a class can implement and extend constructed types:

```

class C<U,V> {}

interface I1<V> {}

class D: C<string,int>, I1<string> {}

class E<T>: C<int,T>, I1<T> {}

```

The base interfaces of a generic class declaration must satisfy the uniqueness rule described in [Uniqueness of implemented interfaces](#).

Explicit interface member implementations

For purposes of implementing interfaces, a class or struct may declare *explicit interface member implementations*. An explicit interface member implementation is a method, property, event, or indexer declaration that references a fully qualified interface member name. For example

```

interface IList<T>
{
    T[] GetElements();
}

interface IDictionary<K,V>
{
    V this[K key];
    void Add(K key, V value);
}

class List<T>: IList<T>, IDictionary<int,T>
{
    T[] IList<T>.GetElements() {...}
    T IDictionary<int,T>.this[int index] {...}
    void IDictionary<int,T>.Add(int index, T value) {...}
}

```

Here `IDictionary<int,T>.this` and `IDictionary<int,T>.Add` are explicit interface member implementations.

In some cases, the name of an interface member may not be appropriate for the implementing class, in which case the interface member may be implemented using explicit interface member implementation. A class implementing a file abstraction, for example, would likely implement a `Close` member function that has the effect of releasing the file resource, and implement the `Dispose` method of the `IDisposable` interface using explicit interface member implementation:

```
interface IDisposable
{
    void Dispose();
}

class MyFile: IDisposable
{
    void IDisposable.Dispose() {
        Close();
    }

    public void Close() {
        // Do what's necessary to close the file
        System.GC.SuppressFinalize(this);
    }
}
```

It is not possible to access an explicit interface member implementation through its fully qualified name in a method invocation, property access, or indexer access. An explicit interface member implementation can only be accessed through an interface instance, and is in that case referenced simply by its member name.

It is a compile-time error for an explicit interface member implementation to include access modifiers, and it is a compile-time error to include the modifiers `abstract`, `virtual`, `override`, or `static`.

Explicit interface member implementations have different accessibility characteristics than other members. Because explicit interface member implementations are never accessible through their fully qualified name in a method invocation or a property access, they are in a sense private. However, since they can be accessed through an interface instance, they are in a sense also public.

Explicit interface member implementations serve two primary purposes:

- Because explicit interface member implementations are not accessible through class or struct instances, they allow interface implementations to be excluded from the public interface of a class or struct. This is particularly useful when a class or struct implements an internal interface that is of no interest to a consumer of that class or struct.
- Explicit interface member implementations allow disambiguation of interface members with the same signature. Without explicit interface member implementations it would be impossible for a class or struct to have different implementations of interface members with the same signature and return type, as would it be impossible for a class or struct to have any implementation at all of interface members with the same signature but with different return types.

For an explicit interface member implementation to be valid, the class or struct must name an interface in its base class list that contains a member whose fully qualified name, type, and parameter types exactly match those of the explicit interface member implementation. Thus, in the following class

```
class Shape: ICloneable
{
    object ICloneable.Clone() {...}
    int IComparable.CompareTo(object other) {...}    // invalid
}
```

the declaration of `Comparable.CompareTo` results in a compile-time error because `Comparable` is not listed in the base class list of `Shape` and is not a base interface of `ICloneable`. Likewise, in the declarations

```
class Shape: ICloneable
{
    object ICloneable.Clone() {...}
}

class Ellipse: Shape
{
    object ICloneable.Clone() {...}    // invalid
}
```

the declaration of `ICloneable.Clone` in `Ellipse` results in a compile-time error because `ICloneable` is not explicitly listed in the base class list of `Ellipse`.

The fully qualified name of an interface member must reference the interface in which the member was declared. Thus, in the declarations

```
interface IControl
{
    void Paint();
}

interface ITextBox: IControl
{
    void SetText(string text);
}

class TextBox: ITextBox
{
    void IControl.Paint() {...}
    void ITextBox.SetText(string text) {...}
}
```

the explicit interface member implementation of `Paint` must be written as `IControl.Paint`.

Uniqueness of implemented interfaces

The interfaces implemented by a generic type declaration must remain unique for all possible constructed types. Without this rule, it would be impossible to determine the correct method to call for certain constructed types. For example, suppose a generic class declaration were permitted to be written as follows:

```
interface I<T>
{
    void F();
}

class X<U,V>: I<U>, I<V>                // Error: I<U> and I<V> conflict
{
    void I<U>.F() {...}
    void I<V>.F() {...}
}
```

Were this permitted, it would be impossible to determine which code to execute in the following case:

```
I<int> x = new X<int,int>();
x.F();
```

To determine if the interface list of a generic type declaration is valid, the following steps are performed:

- Let `L` be the list of interfaces directly specified in a generic class, struct, or interface declaration `C`.
- Add to `L` any base interfaces of the interfaces already in `L`.
- Remove any duplicates from `L`.
- If any possible constructed type created from `C` would, after type arguments are substituted into `L`, cause two interfaces in `L` to be identical, then the declaration of `C` is invalid. Constraint declarations are not considered when determining all possible constructed types.

In the class declaration `x` above, the interface list `L` consists of `I<U>` and `I<V>`. The declaration is invalid because any constructed type with `u` and `v` being the same type would cause these two interfaces to be identical types.

It is possible for interfaces specified at different inheritance levels to unify:

```
interface I<T>
{
    void F();
}

class Base<U>: I<U>
{
    void I<U>.F() {...}
}

class Derived<U,V>: Base<U>, I<V>    // Ok
{
    void I<V>.F() {...}
}
```

This code is valid even though `Derived<U,V>` implements both `I<U>` and `I<V>`. The code

```
I<int> x = new Derived<int,int>();
x.F();
```

invokes the method in `Derived`, since `Derived<int,int>` effectively re-implements `I<int>` ([Interface re-implementation](#)).

Implementation of generic methods

When a generic method implicitly implements an interface method, the constraints given for each method type parameter must be equivalent in both declarations (after any interface type parameters are replaced with the appropriate type arguments), where method type parameters are identified by ordinal positions, left to right.

When a generic method explicitly implements an interface method, however, no constraints are allowed on the implementing method. Instead, the constraints are inherited from the interface method

```

interface I<A,B,C>
{
    void F<T>(T t) where T: A;
    void G<T>(T t) where T: B;
    void H<T>(T t) where T: C;
}

class C: I<object,C,string>
{
    public void F<T>(T t) {...}           // Ok
    public void G<T>(T t) where T: C {...} // Ok
    public void H<T>(T t) where T: string {...} // Error
}

```

The method `C.F<T>` implicitly implements `I<object,C,string>.F<T>`. In this case, `C.F<T>` is not required (nor permitted) to specify the constraint `T:object` since `object` is an implicit constraint on all type parameters. The method `C.G<T>` implicitly implements `I<object,C,string>.G<T>` because the constraints match those in the interface, after the interface type parameters are replaced with the corresponding type arguments. The constraint for method `C.H<T>` is an error because sealed types (`string` in this case) cannot be used as constraints. Omitting the constraint would also be an error since constraints of implicit interface method implementations are required to match. Thus, it is impossible to implicitly implement `I<object,C,string>.H<T>`. This interface method can only be implemented using an explicit interface member implementation:

```

class C: I<object,C,string>
{
    ...

    public void H<U>(U u) where U: class {...}

    void I<object,C,string>.H<T>(T t) {
        string s = t;    // Ok
        H<T>(t);
    }
}

```

In this example, the explicit interface member implementation invokes a public method having strictly weaker constraints. Note that the assignment from `t` to `s` is valid since `T` inherits a constraint of `T:string`, even though this constraint is not expressible in source code.

Interface mapping

A class or struct must provide implementations of all members of the interfaces that are listed in the base class list of the class or struct. The process of locating implementations of interface members in an implementing class or struct is known as *interface mapping*.

Interface mapping for a class or struct `C` locates an implementation for each member of each interface specified in the base class list of `C`. The implementation of a particular interface member `I.M`, where `I` is the interface in which the member `M` is declared, is determined by examining each class or struct `S`, starting with `C` and repeating for each successive base class of `C`, until a match is located:

- If `S` contains a declaration of an explicit interface member implementation that matches `I` and `M`, then this member is the implementation of `I.M`.
- Otherwise, if `S` contains a declaration of a non-static public member that matches `M`, then this member is the implementation of `I.M`. If more than one member matches, it is unspecified which member is the implementation of `I.M`. This situation can only occur if `S` is a constructed type where the two members as declared in the generic type have different signatures, but the type arguments make their signatures identical.

A compile-time error occurs if implementations cannot be located for all members of all interfaces specified in the base class list of `C`. Note that the members of an interface include those members that are inherited from base interfaces.

For purposes of interface mapping, a class member `A` matches an interface member `B` when:

- `A` and `B` are methods, and the name, type, and formal parameter lists of `A` and `B` are identical.
- `A` and `B` are properties, the name and type of `A` and `B` are identical, and `A` has the same accessors as `B` (`A` is permitted to have additional accessors if it is not an explicit interface member implementation).
- `A` and `B` are events, and the name and type of `A` and `B` are identical.
- `A` and `B` are indexers, the type and formal parameter lists of `A` and `B` are identical, and `A` has the same accessors as `B` (`A` is permitted to have additional accessors if it is not an explicit interface member implementation).

Notable implications of the interface mapping algorithm are:

- Explicit interface member implementations take precedence over other members in the same class or struct when determining the class or struct member that implements an interface member.
- Neither non-public nor static members participate in interface mapping.

In the example

```
interface ICloneable
{
    object Clone();
}

class C: ICloneable
{
    object ICloneable.Clone() {...}
    public object Clone() {...}
}
```

the `ICloneable.Clone` member of `C` becomes the implementation of `Clone` in `ICloneable` because explicit interface member implementations take precedence over other members.

If a class or struct implements two or more interfaces containing a member with the same name, type, and parameter types, it is possible to map each of those interface members onto a single class or struct member. For example

```
interface IControl
{
    void Paint();
}

interface IForm
{
    void Paint();
}

class Page: IControl, IForm
{
    public void Paint() {...}
}
```

Here, the `Paint` methods of both `IControl` and `IForm` are mapped onto the `Paint` method in `Page`. It is of course also possible to have separate explicit interface member implementations for the two methods.

If a class or struct implements an interface that contains hidden members, then some members must necessarily be implemented through explicit interface member implementations. For example

```
interface IBase
{
    int P { get; }
}

interface IDerived: IBase
{
    new int P();
}
```

An implementation of this interface would require at least one explicit interface member implementation, and would take one of the following forms

```
class C: IDerived
{
    int IBase.P { get {...} }
    int IDerived.P() {...}
}

class C: IDerived
{
    public int P { get {...} }
    int IDerived.P() {...}
}

class C: IDerived
{
    int IBase.P { get {...} }
    public int P() {...}
}
```

When a class implements multiple interfaces that have the same base interface, there can be only one implementation of the base interface. In the example

```
interface IControl
{
    void Paint();
}

interface ITextBox: IControl
{
    void SetText(string text);
}

interface IListBox: IControl
{
    void SetItems(string[] items);
}

class ComboBox: IControl, ITextBox, IListBox
{
    void IControl.Paint() {...}
    void ITextBox.SetText(string text) {...}
    void IListBox.SetItems(string[] items) {...}
}
```

it is not possible to have separate implementations for the `IControl` named in the base class list, the `IControl` inherited by `ITextBox`, and the `IControl` inherited by `IListBox`. Indeed, there is no notion of a separate

identity for these interfaces. Rather, the implementations of `ITextBox` and `IListBox` share the same implementation of `IControl`, and `ComboBox` is simply considered to implement three interfaces, `IControl`, `ITextBox`, and `IListBox`.

The members of a base class participate in interface mapping. In the example

```
interface Interface1
{
    void F();
}

class Class1
{
    public void F() {}
    public void G() {}
}

class Class2: Class1, Interface1
{
    new public void G() {}
}
```

the method `F` in `Class1` is used in `Class2`'s implementation of `Interface1`.

Interface implementation inheritance

A class inherits all interface implementations provided by its base classes.

Without explicitly *re-implementing* an interface, a derived class cannot in any way alter the interface mappings it inherits from its base classes. For example, in the declarations

```
interface IControl
{
    void Paint();
}

class Control: IControl
{
    public void Paint() {...}
}

class TextBox: Control
{
    new public void Paint() {...}
}
```

the `Paint` method in `TextBox` hides the `Paint` method in `Control`, but it does not alter the mapping of `Control.Paint` onto `IControl.Paint`, and calls to `Paint` through class instances and interface instances will have the following effects

```
Control c = new Control();
TextBox t = new TextBox();
IControl ic = c;
IControl it = t;

c.Paint();           // invokes Control.Paint();
t.Paint();           // invokes TextBox.Paint();
ic.Paint();          // invokes Control.Paint();
it.Paint();          // invokes Control.Paint();
```

However, when an interface method is mapped onto a virtual method in a class, it is possible for derived classes to override the virtual method and alter the implementation of the interface. For example, rewriting the

declarations above to

```
interface IControl
{
    void Paint();
}

class Control: IControl
{
    public virtual void Paint() {...}
}

class TextBox: Control
{
    public override void Paint() {...}
}
```

the following effects will now be observed

```
Control c = new Control();
TextBox t = new TextBox();
IControl ic = c;
IControl it = t;
c.Paint();           // invokes Control.Paint();
t.Paint();           // invokes TextBox.Paint();
ic.Paint();          // invokes Control.Paint();
it.Paint();          // invokes TextBox.Paint();
```

Since explicit interface member implementations cannot be declared virtual, it is not possible to override an explicit interface member implementation. However, it is perfectly valid for an explicit interface member implementation to call another method, and that other method can be declared virtual to allow derived classes to override it. For example

```
interface IControl
{
    void Paint();
}

class Control: IControl
{
    void IControl.Paint() { PaintControl(); }
    protected virtual void PaintControl() {...}
}

class TextBox: Control
{
    protected override void PaintControl() {...}
}
```

Here, classes derived from `Control` can specialize the implementation of `IControl.Paint` by overriding the `PaintControl` method.

Interface re-implementation

A class that inherits an interface implementation is permitted to *re-implement* the interface by including it in the base class list.

A re-implementation of an interface follows exactly the same interface mapping rules as an initial implementation of an interface. Thus, the inherited interface mapping has no effect whatsoever on the interface mapping established for the re-implementation of the interface. For example, in the declarations

```

interface IControl
{
    void Paint();
}

class Control: IControl
{
    void IControl.Paint() {...}
}

class MyControl: Control, IControl
{
    public void Paint() {}
}

```

the fact that `Control` maps `IControl.Paint` onto `Control.IControl.Paint` doesn't affect the re-implementation in `MyControl`, which maps `IControl.Paint` onto `MyControl.Paint`.

Inherited public member declarations and inherited explicit interface member declarations participate in the interface mapping process for re-implemented interfaces. For example

```

interface IMethods
{
    void F();
    void G();
    void H();
    void I();
}

class Base: IMethods
{
    void IMethods.F() {}
    void IMethods.G() {}
    public void H() {}
    public void I() {}
}

class Derived: Base, IMethods
{
    public void F() {}
    void IMethods.H() {}
}

```

Here, the implementation of `IMethods` in `Derived` maps the interface methods onto `Derived.F`, `Base.IMethods.G`, `Derived.IMethods.H`, and `Base.I`.

When a class implements an interface, it implicitly also implements all of that interface's base interfaces. Likewise, a re-implementation of an interface is also implicitly a re-implementation of all of the interface's base interfaces. For example

```

interface IBase
{
    void F();
}

interface IDerived: IBase
{
    void G();
}

class C: IDerived
{
    void IBase.F() {...}
    void IDerived.G() {...}
}

class D: C, IDerived
{
    public void F() {...}
    public void G() {...}
}

```

Here, the re-implementation of `IDerived` also re-implements `IBase`, mapping `IBase.F` onto `D.F`.

Abstract classes and interfaces

Like a non-abstract class, an abstract class must provide implementations of all members of the interfaces that are listed in the base class list of the class. However, an abstract class is permitted to map interface methods onto abstract methods. For example

```

interface IMethods
{
    void F();
    void G();
}

abstract class C: IMethods
{
    public abstract void F();
    public abstract void G();
}

```

Here, the implementation of `IMethods` maps `F` and `G` onto abstract methods, which must be overridden in non-abstract classes that derive from `C`.

Note that explicit interface member implementations cannot be abstract, but explicit interface member implementations are of course permitted to call abstract methods. For example

```

interface IMethods
{
    void F();
    void G();
}

abstract class C: IMethods
{
    void IMethods.F() { FF(); }
    void IMethods.G() { GG(); }
    protected abstract void FF();
    protected abstract void GG();
}

```

Here, non-abstract classes that derive from `C` would be required to override `FF` and `GG`, thus providing the actual implementation of `IMethods`.

Enums

12/28/2021 • 6 minutes to read • [Edit Online](#)

An **enum type** is a distinct value type ([Value types](#)) that declares a set of named constants.

The example

```
enum Color
{
    Red,
    Green,
    Blue
}
```

declares an enum type named `Color` with members `Red`, `Green`, and `Blue`.

Enum declarations

An enum declaration declares a new enum type. An enum declaration begins with the keyword `enum`, and defines the name, accessibility, underlying type, and members of the enum.

```
enum_declaration
: attributes? enum_modifier* 'enum' identifier enum_base? enum_body ';'
;

enum_base
: ':' integral_type
;

enum_body
: '{' enum_member_declarations? '}'
| '{' enum_member_declarations ',' '}'
;
```

Each enum type has a corresponding integral type called the **underlying type** of the enum type. This underlying type must be able to represent all the enumerator values defined in the enumeration. An enum declaration may explicitly declare an underlying type of `byte`, `sbyte`, `short`, `ushort`, `int`, `uint`, `long` or `ulong`. Note that `char` cannot be used as an underlying type. An enum declaration that does not explicitly declare an underlying type has an underlying type of `int`.

The example

```
enum Color: long
{
    Red,
    Green,
    Blue
}
```

declares an enum with an underlying type of `long`. A developer might choose to use an underlying type of `long`, as in the example, to enable the use of values that are in the range of `long` but not in the range of `int`, or to preserve this option for the future.

Enum modifiers

An *enum_declaration* may optionally include a sequence of enum modifiers:

```
enum_modifier
: 'new'
| 'public'
| 'protected'
| 'internal'
| 'private'
;
```

It is a compile-time error for the same modifier to appear multiple times in an enum declaration.

The modifiers of an enum declaration have the same meaning as those of a class declaration ([Class modifiers](#)).

Note, however, that the `abstract` and `sealed` modifiers are not permitted in an enum declaration. Enums cannot be abstract and do not permit derivation.

Enum members

The body of an enum type declaration defines zero or more enum members, which are the named constants of the enum type. No two enum members can have the same name.

```
enum_member_declarations
: enum_member_declaration (',' enum_member_declaration)*
;

enum_member_declaration
: attributes? identifier ('=' constant_expression)?
;
```

Each enum member has an associated constant value. The type of this value is the underlying type for the containing enum. The constant value for each enum member must be in the range of the underlying type for the enum. The example

```
enum Color: uint
{
    Red = -1,
    Green = -2,
    Blue = -3
}
```

results in a compile-time error because the constant values `-1`, `-2`, and `-3` are not in the range of the underlying integral type `uint`.

Multiple enum members may share the same associated value. The example

```
enum Color
{
    Red,
    Green,
    Blue,

    Max = Blue
}
```

shows an enum in which two enum members -- `Blue` and `Max` -- have the same associated value.

The associated value of an enum member is assigned either implicitly or explicitly. If the declaration of the enum member has a *constant_expression* initializer, the value of that constant expression, implicitly converted to the underlying type of the enum, is the associated value of the enum member. If the declaration of the enum member has no initializer, its associated value is set implicitly, as follows:

- If the enum member is the first enum member declared in the enum type, its associated value is zero.
- Otherwise, the associated value of the enum member is obtained by increasing the associated value of the textually preceding enum member by one. This increased value must be within the range of values that can be represented by the underlying type, otherwise a compile-time error occurs.

The example

```
using System;

enum Color
{
    Red,
    Green = 10,
    Blue
}

class Test
{
    static void Main() {
        Console.WriteLine(StringFromColor(Color.Red));
        Console.WriteLine(StringFromColor(Color.Green));
        Console.WriteLine(StringFromColor(Color.Blue));
    }

    static string StringFromColor(Color c) {
        switch (c) {
            case Color.Red:
                return String.Format("Red = {0}", (int) c);

            case Color.Green:
                return String.Format("Green = {0}", (int) c);

            case Color.Blue:
                return String.Format("Blue = {0}", (int) c);

            default:
                return "Invalid color";
        }
    }
}
```

prints out the enum member names and their associated values. The output is:

```
Red = 0
Green = 10
Blue = 11
```

for the following reasons:

- the enum member `Red` is automatically assigned the value zero (since it has no initializer and is the first enum member);
- the enum member `Green` is explicitly given the value `10`;
- and the enum member `Blue` is automatically assigned the value one greater than the member that textually precedes it.

The associated value of an enum member may not, directly or indirectly, use the value of its own associated enum member. Other than this circularity restriction, enum member initializers may freely refer to other enum member initializers, regardless of their textual position. Within an enum member initializer, values of other enum members are always treated as having the type of their underlying type, so that casts are not necessary when referring to other enum members.

The example

```
enum Circular
{
    A = B,
    B
}
```

results in a compile-time error because the declarations of `A` and `B` are circular. `A` depends on `B` explicitly, and `B` depends on `A` implicitly.

Enum members are named and scoped in a manner exactly analogous to fields within classes. The scope of an enum member is the body of its containing enum type. Within that scope, enum members can be referred to by their simple name. From all other code, the name of an enum member must be qualified with the name of its enum type. Enum members do not have any declared accessibility -- an enum member is accessible if its containing enum type is accessible.

The System.Enum type

The type `System.Enum` is the abstract base class of all enum types (this is distinct and different from the underlying type of the enum type), and the members inherited from `System.Enum` are available in any enum type. A boxing conversion ([Boxing conversions](#)) exists from any enum type to `System.Enum`, and an unboxing conversion ([Unboxing conversions](#)) exists from `System.Enum` to any enum type.

Note that `System.Enum` is not itself an *enum_type*. Rather, it is a *class_type* from which all *enum_types* are derived. The type `System.Enum` inherits from the type `System.ValueType` ([The System.ValueType type](#)), which, in turn, inherits from type `object`. At run-time, a value of type `System.Enum` can be `null` or a reference to a boxed value of any enum type.

Enum values and operations

Each enum type defines a distinct type; an explicit enumeration conversion ([Explicit enumeration conversions](#)) is required to convert between an enum type and an integral type, or between two enum types. The set of values that an enum type can take on is not limited by its enum members. In particular, any value of the underlying type of an enum can be cast to the enum type, and is a distinct valid value of that enum type.

Enum members have the type of their containing enum type (except within other enum member initializers: see [Enum members](#)). The value of an enum member declared in enum type `E` with associated value `v` is `(E)v`.

The following operators can be used on values of enum types: `==`, `!=`, `<`, `>`, `<=`, `>=` ([Enumeration comparison operators](#)), binary `+` ([Addition operator](#)), binary `-` ([Subtraction operator](#)), `^`, `&`, `|` ([Enumeration logical operators](#)), `~` ([Bitwise complement operator](#)), `++` and `--` ([Postfix increment and decrement operators](#) and [Prefix increment and decrement operators](#)).

Every enum type automatically derives from the class `System.Enum` (which, in turn, derives from `System.ValueType` and `object`). Thus, inherited methods and properties of this class can be used on values of an enum type.

Delegates

12/28/2021 • 9 minutes to read • [Edit Online](#)

Delegates enable scenarios that other languages—such as C++, Pascal, and Modula -- have addressed with function pointers. Unlike C++ function pointers, however, delegates are fully object oriented, and unlike C++ pointers to member functions, delegates encapsulate both an object instance and a method.

A delegate declaration defines a class that is derived from the class `System.Delegate`. A delegate instance encapsulates an invocation list, which is a list of one or more methods, each of which is referred to as a callable entity. For instance methods, a callable entity consists of an instance and a method on that instance. For static methods, a callable entity consists of just a method. Invoking a delegate instance with an appropriate set of arguments causes each of the delegate's callable entities to be invoked with the given set of arguments.

An interesting and useful property of a delegate instance is that it does not know or care about the classes of the methods it encapsulates; all that matters is that those methods be compatible ([Delegate declarations](#)) with the delegate's type. This makes delegates perfectly suited for "anonymous" invocation.

Delegate declarations

A *delegate_declaration* is a *type_declaration* ([Type declarations](#)) that declares a new delegate type.

```
delegate_declaration
: attributes? delegate_modifier* 'delegate' return_type
  identifier variant_type_parameter_list?
  '(' formal_parameter_list? ')' type_parameter_constraints_clause* ';'
;

delegate_modifier
: 'new'
| 'public'
| 'protected'
| 'internal'
| 'private'
| delegate_modifier_unsafe
;
```

It is a compile-time error for the same modifier to appear multiple times in a delegate declaration.

The `new` modifier is only permitted on delegates declared within another type, in which case it specifies that such a delegate hides an inherited member by the same name, as described in [The new modifier](#).

The `public`, `protected`, `internal`, and `private` modifiers control the accessibility of the delegate type. Depending on the context in which the delegate declaration occurs, some of these modifiers may not be permitted ([Declared accessibility](#)).

The delegate's type name is *identifier*.

The optional *formal_parameter_list* specifies the parameters of the delegate, and *return_type* indicates the return type of the delegate.

The optional *variant_type_parameter_list* ([Variant type parameter lists](#)) specifies the type parameters to the delegate itself.

The return type of a delegate type must be either `void`, or output-safe ([Variance safety](#)).

All the formal parameter types of a delegate type must be input-safe. Additionally, any `out` or `ref` parameter types must also be output-safe. Note that even `out` parameters are required to be input-safe, due to a limitation of the underlying execution platform.

Delegate types in C# are name equivalent, not structurally equivalent. Specifically, two different delegate types that have the same parameter lists and return type are considered different delegate types. However, instances of two distinct but structurally equivalent delegate types may compare as equal ([Delegate equality operators](#)).

For example:

```
delegate int D1(int i, double d);

class A
{
    public static int M1(int a, double b) {...}
}

class B
{
    delegate int D2(int c, double d);
    public static int M1(int f, double g) {...}
    public static void M2(int k, double l) {...}
    public static int M3(int g) {...}
    public static void M4(int g) {...}
}
```

The methods `A.M1` and `B.M1` are compatible with both the delegate types `D1` and `D2`, since they have the same return type and parameter list; however, these delegate types are two different types, so they are not interchangeable. The methods `B.M2`, `B.M3`, and `B.M4` are incompatible with the delegate types `D1` and `D2`, since they have different return types or parameter lists.

Like other generic type declarations, type arguments must be given to create a constructed delegate type. The parameter types and return type of a constructed delegate type are created by substituting, for each type parameter in the delegate declaration, the corresponding type argument of the constructed delegate type. The resulting return type and parameter types are used in determining what methods are compatible with a constructed delegate type. For example:

```
delegate bool Predicate<T>(T value);

class X
{
    static bool F(int i) {...}
    static bool G(string s) {...}
}
```

The method `X.F` is compatible with the delegate type `Predicate<int>` and the method `X.G` is compatible with the delegate type `Predicate<string>`.

The only way to declare a delegate type is via a *delegate declaration*. A delegate type is a class type that is derived from `System.Delegate`. Delegate types are implicitly `sealed`, so it is not permissible to derive any type from a delegate type. It is also not permissible to derive a non-delegate class type from `System.Delegate`. Note that `System.Delegate` is not itself a delegate type; it is a class type from which all delegate types are derived.

C# provides special syntax for delegate instantiation and invocation. Except for instantiation, any operation that can be applied to a class or class instance can also be applied to a delegate class or instance, respectively. In particular, it is possible to access members of the `System.Delegate` type via the usual member access syntax.

The set of methods encapsulated by a delegate instance is called an invocation list. When a delegate instance is

created ([Delegate compatibility](#)) from a single method, it encapsulates that method, and its invocation list contains only one entry. However, when two non-null delegate instances are combined, their invocation lists are concatenated -- in the order left operand then right operand -- to form a new invocation list, which contains two or more entries.

Delegates are combined using the binary `+` ([Addition operator](#)) and `+=` operators ([Compound assignment](#)). A delegate can be removed from a combination of delegates, using the binary `-` ([Subtraction operator](#)) and `-=` operators ([Compound assignment](#)). Delegates can be compared for equality ([Delegate equality operators](#)).

The following example shows the instantiation of a number of delegates, and their corresponding invocation lists:

```
delegate void D(int x);

class C
{
    public static void M1(int i) {...}
    public static void M2(int i) {...}
}

class Test
{
    static void Main() {
        D cd1 = new D(C.M1);           // M1
        D cd2 = new D(C.M2);           // M2
        D cd3 = cd1 + cd2;              // M1 + M2
        D cd4 = cd3 + cd1;              // M1 + M2 + M1
        D cd5 = cd4 + cd3;              // M1 + M2 + M1 + M1 + M2
    }
}
```

When `cd1` and `cd2` are instantiated, they each encapsulate one method. When `cd3` is instantiated, it has an invocation list of two methods, `M1` and `M2`, in that order. `cd4`'s invocation list contains `M1`, `M2`, and `M1`, in that order. Finally, `cd5`'s invocation list contains `M1`, `M2`, `M1`, `M1`, and `M2`, in that order. For more examples of combining (as well as removing) delegates, see [Delegate invocation](#).

Delegate compatibility

A method or delegate `M` is *compatible* with a delegate type `D` if all of the following are true:

- `D` and `M` have the same number of parameters, and each parameter in `D` has the same `ref` or `out` modifiers as the corresponding parameter in `M`.
- For each value parameter (a parameter with no `ref` or `out` modifier), an identity conversion ([Identity conversion](#)) or implicit reference conversion ([Implicit reference conversions](#)) exists from the parameter type in `D` to the corresponding parameter type in `M`.
- For each `ref` or `out` parameter, the parameter type in `D` is the same as the parameter type in `M`.
- An identity or implicit reference conversion exists from the return type of `M` to the return type of `D`.

Delegate instantiation

An instance of a delegate is created by a *delegate_creation_expression* ([Delegate creation expressions](#)) or a conversion to a delegate type. The newly created delegate instance then refers to either:

- The static method referenced in the *delegate_creation_expression*, or
- The target object (which cannot be `null`) and instance method referenced in the

delegate_creation_expression, or

- Another delegate.

For example:

```
delegate void D(int x);

class C
{
    public static void M1(int i) {...}
    public void M2(int i) {...}
}

class Test
{
    static void Main() {
        D cd1 = new D(C.M1);           // static method
        C t = new C();
        D cd2 = new D(t.M2);           // instance method
        D cd3 = new D(cd2);            // another delegate
    }
}
```

Once instantiated, delegate instances always refer to the same target object and method. Remember, when two delegates are combined, or one is removed from another, a new delegate results with its own invocation list; the invocation lists of the delegates combined or removed remain unchanged.

Delegate invocation

C# provides special syntax for invoking a delegate. When a non-null delegate instance whose invocation list contains one entry is invoked, it invokes the one method with the same arguments it was given, and returns the same value as the referred to method. (See [Delegate invocations](#) for detailed information on delegate invocation.) If an exception occurs during the invocation of such a delegate, and that exception is not caught within the method that was invoked, the search for an exception catch clause continues in the method that called the delegate, as if that method had directly called the method to which that delegate referred.

Invocation of a delegate instance whose invocation list contains multiple entries proceeds by invoking each of the methods in the invocation list, synchronously, in order. Each method so called is passed the same set of arguments as was given to the delegate instance. If such a delegate invocation includes reference parameters ([Reference parameters](#)), each method invocation will occur with a reference to the same variable; changes to that variable by one method in the invocation list will be visible to methods further down the invocation list. If the delegate invocation includes output parameters or a return value, their final value will come from the invocation of the last delegate in the list.

If an exception occurs during processing of the invocation of such a delegate, and that exception is not caught within the method that was invoked, the search for an exception catch clause continues in the method that called the delegate, and any methods further down the invocation list are not invoked.

Attempting to invoke a delegate instance whose value is null results in an exception of type

```
System.NullReferenceException .
```

The following example shows how to instantiate, combine, remove, and invoke delegates:

```

using System;

delegate void D(int x);

class C
{
    public static void M1(int i) {
        Console.WriteLine("C.M1: " + i);
    }

    public static void M2(int i) {
        Console.WriteLine("C.M2: " + i);
    }

    public void M3(int i) {
        Console.WriteLine("C.M3: " + i);
    }
}

class Test
{
    static void Main() {
        D cd1 = new D(C.M1);
        cd1(-1);           // call M1

        D cd2 = new D(C.M2);
        cd2(-2);           // call M2

        D cd3 = cd1 + cd2;
        cd3(10);           // call M1 then M2

        cd3 += cd1;
        cd3(20);           // call M1, M2, then M1

        C c = new C();
        D cd4 = new D(c.M3);
        cd3 += cd4;
        cd3(30);           // call M1, M2, M1, then M3

        cd3 -= cd1;         // remove last M1
        cd3(40);           // call M1, M2, then M3

        cd3 -= cd4;
        cd3(50);           // call M1 then M2

        cd3 -= cd2;
        cd3(60);           // call M1

        cd3 -= cd2;         // impossible removal is benign
        cd3(60);           // call M1

        cd3 -= cd1;         // invocation list is empty so cd3 is null

        cd3(70);           // System.NullReferenceException thrown

        cd3 -= cd1;         // impossible removal is benign
    }
}

```

As shown in the statement `cd3 += cd1;`, a delegate can be present in an invocation list multiple times. In this case, it is simply invoked once per occurrence. In an invocation list such as this, when that delegate is removed, the last occurrence in the invocation list is the one actually removed.

Immediately prior to the execution of the final statement, `cd3 -= cd1;`, the delegate `cd3` refers to an empty invocation list. Attempting to remove a delegate from an empty list (or to remove a non-existent delegate from

a non-empty list) is not an error.

The output produced is:

```
C.M1: -1  
C.M2: -2  
C.M1: 10  
C.M2: 10  
C.M1: 20  
C.M2: 20  
C.M1: 20  
C.M1: 30  
C.M2: 30  
C.M1: 30  
C.M3: 30  
C.M1: 40  
C.M2: 40  
C.M3: 40  
C.M1: 50  
C.M2: 50  
C.M1: 60  
C.M1: 60
```

Exceptions

12/28/2021 • 4 minutes to read • [Edit Online](#)

Exceptions in C# provide a structured, uniform, and type-safe way of handling both system level and application level error conditions. The exception mechanism in C# is quite similar to that of C++, with a few important differences:

- In C#, all exceptions must be represented by an instance of a class type derived from `System.Exception`. In C++, any value of any type can be used to represent an exception.
- In C#, a finally block ([The try statement](#)) can be used to write termination code that executes in both normal execution and exceptional conditions. Such code is difficult to write in C++ without duplicating code.
- In C#, system-level exceptions such as overflow, divide-by-zero, and null dereferences have well defined exception classes and are on a par with application-level error conditions.

Causes of exceptions

Exception can be thrown in two different ways.

- A `throw` statement ([The throw statement](#)) throws an exception immediately and unconditionally. Control never reaches the statement immediately following the `throw`.
- Certain exceptional conditions that arise during the processing of C# statements and expression cause an exception in certain circumstances when the operation cannot be completed normally. For example, an integer division operation ([Division operator](#)) throws a `System.DivideByZeroException` if the denominator is zero. See [Common Exception Classes](#) for a list of the various exceptions that can occur in this way.

The System.Exception class

The `System.Exception` class is the base type of all exceptions. This class has a few notable properties that all exceptions share:

- `Message` is a read-only property of type `string` that contains a human-readable description of the reason for the exception.
- `InnerException` is a read-only property of type `Exception`. If its value is non-null, it refers to the exception that caused the current exception—that is, the current exception was raised in a catch block handling the `InnerException`. Otherwise, its value is null, indicating that this exception was not caused by another exception. The number of exception objects chained together in this manner can be arbitrary.

The value of these properties can be specified in calls to the instance constructor for `System.Exception`.

How exceptions are handled

Exceptions are handled by a `try` statement ([The try statement](#)).

When an exception occurs, the system searches for the nearest `catch` clause that can handle the exception, as determined by the run-time type of the exception. First, the current method is searched for a lexically enclosing `try` statement, and the associated catch clauses of the try statement are considered in order. If that fails, the method that called the current method is searched for a lexically enclosing `try` statement that encloses the point of the call to the current method. This search continues until a `catch` clause is found that can handle the current exception, by naming an exception class that is of the same class, or a base class, of the run-time type of the exception being thrown. A `catch` clause that doesn't name an exception class can handle any exception.

Once a matching catch clause is found, the system prepares to transfer control to the first statement of the catch clause. Before execution of the catch clause begins, the system first executes, in order, any `finally` clauses that were associated with try statements more nested than the one that caught the exception.

If no matching catch clause is found, one of two things occurs:

- If the search for a matching catch clause reaches a static constructor ([Static constructors](#)) or static field initializer, then a `System.TypeInitializationException` is thrown at the point that triggered the invocation of the static constructor. The inner exception of the `System.TypeInitializationException` contains the exception that was originally thrown.
- If the search for matching catch clauses reaches the code that initially started the thread, then execution of the thread is terminated. The impact of such termination is implementation-defined.

Exceptions that occur during destructor execution are worth special mention. If an exception occurs during destructor execution, and that exception is not caught, then the execution of that destructor is terminated and the destructor of the base class (if any) is called. If there is no base class (as in the case of the `object` type) or if there is no base class destructor, then the exception is discarded.

Common Exception Classes

The following exceptions are thrown by certain C# operations.

EXCEPTION TYPE	DESCRIPTION
<code>System.ArithmeticException</code>	A base class for exceptions that occur during arithmetic operations, such as <code>System.DivideByZeroException</code> and <code>System.OverflowException</code> .
<code>System.ArrayTypeMismatchException</code>	Thrown when a store into an array fails because the actual type of the stored element is incompatible with the actual type of the array.
<code>System.DivideByZeroException</code>	Thrown when an attempt to divide an integral value by zero occurs.
<code>System.IndexOutOfRangeException</code>	Thrown when an attempt to index an array via an index that is less than zero or outside the bounds of the array.
<code>System.InvalidCastException</code>	Thrown when an explicit conversion from a base type or interface to a derived type fails at run time.
<code>System.NullReferenceException</code>	Thrown when a <code>null</code> reference is used in a way that causes the referenced object to be required.
<code>System.OutOfMemoryException</code>	Thrown when an attempt to allocate memory (via <code>new</code>) fails.
<code>System.OverflowException</code>	Thrown when an arithmetic operation in a <code>checked</code> context overflows.
<code>System.StackOverflowException</code>	Thrown when the execution stack is exhausted by having too many pending method calls; typically indicative of very deep or unbounded recursion.

EXCEPTION TYPE	DESCRIPTION
<code>System.TypeInitializationException</code>	Thrown when a static constructor throws an exception, and no <code>catch</code> clauses exists to catch it.

Attributes

12/28/2021 • 25 minutes to read • [Edit Online](#)

Much of the C# language enables the programmer to specify declarative information about the entities defined in the program. For example, the accessibility of a method in a class is specified by decorating it with the *method_modifiers* `public`, `protected`, `internal`, and `private`.

C# enables programmers to invent new kinds of declarative information, called **attributes**. Programmers can then attach attributes to various program entities, and retrieve attribute information in a run-time environment. For instance, a framework might define a `HelpAttribute` attribute that can be placed on certain program elements (such as classes and methods) to provide a mapping from those program elements to their documentation.

Attributes are defined through the declaration of attribute classes ([Attribute classes](#)), which may have positional and named parameters ([Positional and named parameters](#)). Attributes are attached to entities in a C# program using attribute specifications ([Attribute specification](#)), and can be retrieved at run-time as attribute instances ([Attribute instances](#)).

Attribute classes

A class that derives from the abstract class `System.Attribute`, whether directly or indirectly, is an **attribute class**. The declaration of an attribute class defines a new kind of **attribute** that can be placed on a declaration. By convention, attribute classes are named with a suffix of `Attribute`. Uses of an attribute may either include or omit this suffix.

Attribute usage

The attribute `AttributeUsage` ([The AttributeUsage attribute](#)) is used to describe how an attribute class can be used.

`AttributeUsage` has a positional parameter ([Positional and named parameters](#)) that enables an attribute class to specify the kinds of declarations on which it can be used. The example

```
using System;

[AttributeUsage(AttributeTargets.Class | AttributeTargets.Interface)]
public class SimpleAttribute: Attribute
{
    ...
}
```

defines an attribute class named `SimpleAttribute` that can be placed on *class_declarations* and *interface_declarations* only. The example

```
[Simple] class Class1 {...}

[Simple] interface Interface1 {...}
```

shows several uses of the `Simple` attribute. Although this attribute is defined with the name `SimpleAttribute`, when this attribute is used, the `Attribute` suffix may be omitted, resulting in the short name `Simple`. Thus, the example above is semantically equivalent to the following:

```
[SimpleAttribute] class Class1 {...}

[SimpleAttribute] interface Interface1 {...}
```

`AttributeUsage` has a named parameter ([Positional and named parameters](#)) called `AllowMultiple`, which indicates whether the attribute can be specified more than once for a given entity. If `AllowMultiple` for an attribute class is true, then that attribute class is a *multi-use attribute class*, and can be specified more than once on an entity. If `AllowMultiple` for an attribute class is false or it is unspecified, then that attribute class is a *single-use attribute class*, and can be specified at most once on an entity.

The example

```
using System;

[AttributeUsage(AttributeTargets.Class, AllowMultiple = true)]
public class AuthorAttribute: Attribute
{
    private string name;

    public AuthorAttribute(string name) {
        this.name = name;
    }

    public string Name {
        get { return name; }
    }
}
```

defines a multi-use attribute class named `AuthorAttribute`. The example

```
[Author("Brian Kernighan"), Author("Dennis Ritchie")]
class Class1
{
    ...
}
```

shows a class declaration with two uses of the `Author` attribute.

`AttributeUsage` has another named parameter called `Inherited`, which indicates whether the attribute, when specified on a base class, is also inherited by classes that derive from that base class. If `Inherited` for an attribute class is true, then that attribute is inherited. If `Inherited` for an attribute class is false then that attribute is not inherited. If it is unspecified, its default value is true.

An attribute class `X` not having an `AttributeUsage` attribute attached to it, as in

```
using System;

class X: Attribute {...}
```

is equivalent to the following:

```
using System;

[AttributeUsage(
    AttributeTargets.All,
    AllowMultiple = false,
    Inherited = true)
]
class X: Attribute {...}
```

Positional and named parameters

Attribute classes can have *positional parameters* and *named parameters*. Each public instance constructor for an attribute class defines a valid sequence of positional parameters for that attribute class. Each non-static public read-write field and property for an attribute class defines a named parameter for the attribute class.

The example

```
using System;

[AttributeUsage(AttributeTargets.Class)]
public class HelpAttribute: Attribute
{
    public HelpAttribute(string url) {           // Positional parameter
        ...
    }

    public string Topic {                       // Named parameter
        get {...}
        set {...}
    }

    public string Url {
        get {...}
    }
}
```

defines an attribute class named `HelpAttribute` that has one positional parameter, `url`, and one named parameter, `Topic`. Although it is non-static and public, the property `url` does not define a named parameter, since it is not read-write.

This attribute class might be used as follows:

```
[Help("http://www.mycompany.com/.../Class1.htm")]
class Class1
{
    ...
}

[Help("http://www.mycompany.com/.../Misc.htm", Topic = "Class2")]
class Class2
{
    ...
}
```

Attribute parameter types

The types of positional and named parameters for an attribute class are limited to the *attribute parameter types*, which are:

- One of the following types: `bool`, `byte`, `char`, `double`, `float`, `int`, `long`, `sbyte`, `short`, `string`, `uint`, `ulong`, `ushort`.

- The type `object` .
- The type `System.Type` .
- An enum type, provided it has public accessibility and the types in which it is nested (if any) also have public accessibility ([Attribute specification](#)).
- Single-dimensional arrays of the above types.
- A constructor argument or public field which does not have one of these types, cannot be used as a positional or named parameter in an attribute specification.

Attribute specification

Attribute specification is the application of a previously defined attribute to a declaration. An attribute is a piece of additional declarative information that is specified for a declaration. Attributes can be specified at global scope (to specify attributes on the containing assembly or module) and for *type_declarations* ([Type declarations](#)), *class_member_declarations* ([Type parameter constraints](#)), *interface_member_declarations* ([Interface members](#)), *struct_member_declarations* ([Struct members](#)), *enum_member_declarations* ([Enum members](#)), *accessor_declarations* ([Accessors](#)), *event_accessor_declarations* ([Field-like events](#)), and *formal_parameter_lists* ([Method parameters](#)).

Attributes are specified in **attribute sections**. An attribute section consists of a pair of square brackets, which surround a comma-separated list of one or more attributes. The order in which attributes are specified in such a list, and the order in which sections attached to the same program entity are arranged, is not significant. For instance, the attribute specifications `[A][B]` , `[B][A]` , `[A,B]` , and `[B,A]` are equivalent.

```
global_attributes
: global_attribute_section+
;

global_attribute_section
: '[' global_attribute_target_specifier attribute_list ']'
| '[' global_attribute_target_specifier attribute_list ',' ']'
;

global_attribute_target_specifier
: global_attribute_target ':'
;

global_attribute_target
: 'assembly'
| 'module'
;

attributes
: attribute_section+
;

attribute_section
: '[' attribute_target_specifier? attribute_list ']'
| '[' attribute_target_specifier? attribute_list ',' ']'
;

attribute_target_specifier
: attribute_target ':'
;

attribute_target
: 'field'
| 'event'
| 'method'
| 'param'
| 'property'
| 'return'
```

```

    | 'type'
    ;

attribute_list
    : attribute (',' attribute)*
    ;

attribute
    : attribute_name attribute_arguments?
    ;

attribute_name
    : type_name
    ;

attribute_arguments
    : '(' positional_argument_list? ')'
    | '(' positional_argument_list ',' named_argument_list ')'
    | '(' named_argument_list ')'
    ;

positional_argument_list
    : positional_argument (',' positional_argument)*
    ;

positional_argument
    : attribute_argument_expression
    ;

named_argument_list
    : named_argument (',' named_argument)*
    ;

named_argument
    : identifier '=' attribute_argument_expression
    ;

attribute_argument_expression
    : expression
    ;

```

An attribute consists of an *attribute_name* and an optional list of positional and named arguments. The positional arguments (if any) precede the named arguments. A positional argument consists of an *attribute_argument_expression*; a named argument consists of a name, followed by an equal sign, followed by an *attribute_argument_expression*, which, together, are constrained by the same rules as simple assignment. The order of named arguments is not significant.

The *attribute_name* identifies an attribute class. If the form of *attribute_name* is *type_name* then this name must refer to an attribute class. Otherwise, a compile-time error occurs. The example

```

class Class1 {}

[Class1] class Class2 {}    // Error

```

results in a compile-time error because it attempts to use `Class1` as an attribute class when `Class1` is not an attribute class.

Certain contexts permit the specification of an attribute on more than one target. A program can explicitly specify the target by including an *attribute_target_specifier*. When an attribute is placed at the global level, a *global_attribute_target_specifier* is required. In all other locations, a reasonable default is applied, but an *attribute_target_specifier* can be used to affirm or override the default in certain ambiguous cases (or to just affirm the default in non-ambiguous cases). Thus, typically, *attribute_target_specifiers* can be omitted except at

the global level. The potentially ambiguous contexts are resolved as follows:

- An attribute specified at global scope can apply either to the target assembly or the target module. No default exists for this context, so an *attribute_target_specifier* is always required in this context. The presence of the `assembly` *attribute_target_specifier* indicates that the attribute applies to the target assembly; the presence of the `module` *attribute_target_specifier* indicates that the attribute applies to the target module.
- An attribute specified on a delegate declaration can apply either to the delegate being declared or to its return value. In the absence of an *attribute_target_specifier*, the attribute applies to the delegate. The presence of the `type` *attribute_target_specifier* indicates that the attribute applies to the delegate; the presence of the `return` *attribute_target_specifier* indicates that the attribute applies to the return value.
- An attribute specified on a method declaration can apply either to the method being declared or to its return value. In the absence of an *attribute_target_specifier*, the attribute applies to the method. The presence of the `method` *attribute_target_specifier* indicates that the attribute applies to the method; the presence of the `return` *attribute_target_specifier* indicates that the attribute applies to the return value.
- An attribute specified on an operator declaration can apply either to the operator being declared or to its return value. In the absence of an *attribute_target_specifier*, the attribute applies to the operator. The presence of the `method` *attribute_target_specifier* indicates that the attribute applies to the operator; the presence of the `return` *attribute_target_specifier* indicates that the attribute applies to the return value.
- An attribute specified on an event declaration that omits event accessors can apply to the event being declared, to the associated field (if the event is not abstract), or to the associated add and remove methods. In the absence of an *attribute_target_specifier*, the attribute applies to the event. The presence of the `event` *attribute_target_specifier* indicates that the attribute applies to the event; the presence of the `field` *attribute_target_specifier* indicates that the attribute applies to the field; and the presence of the `method` *attribute_target_specifier* indicates that the attribute applies to the methods.
- An attribute specified on a get accessor declaration for a property or indexer declaration can apply either to the associated method or to its return value. In the absence of an *attribute_target_specifier*, the attribute applies to the method. The presence of the `method` *attribute_target_specifier* indicates that the attribute applies to the method; the presence of the `return` *attribute_target_specifier* indicates that the attribute applies to the return value.
- An attribute specified on a set accessor for a property or indexer declaration can apply either to the associated method or to its lone implicit parameter. In the absence of an *attribute_target_specifier*, the attribute applies to the method. The presence of the `method` *attribute_target_specifier* indicates that the attribute applies to the method; the presence of the `param` *attribute_target_specifier* indicates that the attribute applies to the parameter; the presence of the `return` *attribute_target_specifier* indicates that the attribute applies to the return value.
- An attribute specified on an add or remove accessor declaration for an event declaration can apply either to the associated method or to its lone parameter. In the absence of an *attribute_target_specifier*, the attribute applies to the method. The presence of the `method` *attribute_target_specifier* indicates that the attribute applies to the method; the presence of the `param` *attribute_target_specifier* indicates that the attribute applies to the parameter; the presence of the `return` *attribute_target_specifier* indicates that the attribute applies to the return value.

In other contexts, inclusion of an *attribute_target_specifier* is permitted but unnecessary. For instance, a class declaration may either include or omit the specifier `type`:

```
[type: Author("Brian Kernighan")]
class Class1 {}

[Author("Dennis Ritchie")]
class Class2 {}
```

It is an error to specify an invalid *attribute_target_specifier*. For instance, the specifier `param` cannot be used on

a class declaration:

```
[param: Author("Brian Kernighan")]      // Error
class Class1 {}
```

By convention, attribute classes are named with a suffix of `Attribute`. An *attribute_name* of the form *type_name* may either include or omit this suffix. If an attribute class is found both with and without this suffix, an ambiguity is present, and a compile-time error results. If the *attribute_name* is spelled such that its right-most *identifier* is a verbatim identifier ([Identifiers](#)), then only an attribute without a suffix is matched, thus enabling such an ambiguity to be resolved. The example

```
using System;

[AttributeUsage(AttributeTargets.All)]
public class X: Attribute
{}

[AttributeUsage(AttributeTargets.All)]
public class XAttribute: Attribute
{}

[X]                                // Error: ambiguity
class Class1 {}

[XAttribute]                       // Refers to XAttribute
class Class2 {}

[@X]                              // Refers to X
class Class3 {}

[@XAttribute]                     // Refers to XAttribute
class Class4 {}
```

shows two attribute classes named `X` and `XAttribute`. The attribute `[X]` is ambiguous, since it could refer to either `X` or `XAttribute`. Using a verbatim identifier allows the exact intent to be specified in such rare cases. The attribute `[XAttribute]` is not ambiguous (although it would be if there was an attribute class named `XAttributeAttribute`!). If the declaration for class `X` is removed, then both attributes refer to the attribute class named `XAttribute`, as follows:

```
using System;

[AttributeUsage(AttributeTargets.All)]
public class XAttribute: Attribute
{}

[X]                                // Refers to XAttribute
class Class1 {}

[XAttribute]                       // Refers to XAttribute
class Class2 {}

[@X]                              // Error: no attribute named "X"
class Class3 {}
```

It is a compile-time error to use a single-use attribute class more than once on the same entity. The example

```

using System;

[AttributeUsage(AttributeTargets.Class)]
public class HelpStringAttribute: Attribute
{
    string value;

    public HelpStringAttribute(string value) {
        this.value = value;
    }

    public string Value {
        get {...}
    }
}

[HelpString("Description of Class1")]
[HelpString("Another description of Class1")]
public class Class1 {}

```

results in a compile-time error because it attempts to use `HelpString`, which is a single-use attribute class, more than once on the declaration of `Class1`.

An expression `E` is an *attribute_argument_expression* if all of the following statements are true:

- The type of `E` is an attribute parameter type ([Attribute parameter types](#)).
- At compile-time, the value of `E` can be resolved to one of the following:
 - A constant value.
 - A `System.Type` object.
 - A one-dimensional array of *attribute_argument_expressions*.

For example:

```

using System;

[AttributeUsage(AttributeTargets.Class)]
public class TestAttribute: Attribute
{
    public int P1 {
        get {...}
        set {...}
    }

    public Type P2 {
        get {...}
        set {...}
    }

    public object P3 {
        get {...}
        set {...}
    }
}

[Test(P1 = 1234, P3 = new int[] {1, 3, 5}, P2 = typeof(float))]
class MyClass {}

```

A *typeof_expression* ([The typeof operator](#)) used as an attribute argument expression can reference a non-generic type, a closed constructed type, or an unbound generic type, but it cannot reference an open type. This is to ensure that the expression can be resolved at compile-time.

```

class A: Attribute
{
    public A(Type t) {...}
}

class G<T>
{
    [A(typeof(T))] T t;           // Error, open type in attribute
}

class X
{
    [A(typeof(List<int>))] int x;   // Ok, closed constructed type
    [A(typeof(List<>))] int y;     // Ok, unbound generic type
}

```

Attribute instances

An **attribute instance** is an instance that represents an attribute at run-time. An attribute is defined with an attribute class, positional arguments, and named arguments. An attribute instance is an instance of the attribute class that is initialized with the positional and named arguments.

Retrieval of an attribute instance involves both compile-time and run-time processing, as described in the following sections.

Compilation of an attribute

The compilation of an *attribute* with attribute class `T`, *positional_argument_list* `P` and *named_argument_list* `N`, consists of the following steps:

- Follow the compile-time processing steps for compiling an *object_creation_expression* of the form `new T(P)`. These steps either result in a compile-time error, or determine an instance constructor `C` on `T` that can be invoked at run-time.
- If `C` does not have public accessibility, then a compile-time error occurs.
- For each *named_argument* `Arg` in `N`:
 - Let `Name` be the *identifier* of the *named_argument* `Arg`.
 - `Name` must identify a non-static read-write public field or property on `T`. If `T` has no such field or property, then a compile-time error occurs.
- Keep the following information for run-time instantiation of the attribute: the attribute class `T`, the instance constructor `C` on `T`, the *positional_argument_list* `P` and the *named_argument_list* `N`.

Run-time retrieval of an attribute instance

Compilation of an *attribute* yields an attribute class `T`, an instance constructor `C` on `T`, a *positional_argument_list* `P`, and a *named_argument_list* `N`. Given this information, an attribute instance can be retrieved at run-time using the following steps:

- Follow the run-time processing steps for executing an *object_creation_expression* of the form `new T(P)`, using the instance constructor `C` as determined at compile-time. These steps either result in an exception, or produce an instance `O` of `T`.
- For each *named_argument* `Arg` in `N`, in order:
 - Let `Name` be the *identifier* of the *named_argument* `Arg`. If `Name` does not identify a non-static public read-write field or property on `O`, then an exception is thrown.
 - Let `Value` be the result of evaluating the *attribute_argument_expression* of `Arg`.
 - If `Name` identifies a field on `O`, then set this field to `Value`.
 - Otherwise, `Name` identifies a property on `O`. Set this property to `Value`.

- The result is `o`, an instance of the attribute class `T` that has been initialized with the *positional_argument_list* `P` and the *named_argument_list* `N`.

Reserved attributes

A small number of attributes affect the language in some way. These attributes include:

- `System.AttributeUsageAttribute` ([The AttributeUsage attribute](#)), which is used to describe the ways in which an attribute class can be used.
- `System.Diagnostics.ConditionalAttribute` ([The Conditional attribute](#)), which is used to define conditional methods.
- `System.ObsoleteAttribute` ([The Obsolete attribute](#)), which is used to mark a member as obsolete.
- `System.Runtime.CompilerServices.CallerLineNumberAttribute`, `System.Runtime.CompilerServices.CallerFilePathAttribute` and `System.Runtime.CompilerServices.CallerMemberNameAttribute` ([Caller info attributes](#)), which are used to supply information about the calling context to optional parameters.

The AttributeUsage attribute

The attribute `AttributeUsage` is used to describe the manner in which the attribute class can be used.

A class that is decorated with the `AttributeUsage` attribute must derive from `System.Attribute`, either directly or indirectly. Otherwise, a compile-time error occurs.

```
namespace System
{
    [AttributeUsage(AttributeTargets.Class)]
    public class AttributeUsageAttribute : Attribute
    {
        public AttributeUsageAttribute(AttributeTargets validOn) {...}
        public virtual bool AllowMultiple { get {...} set {...} }
        public virtual bool Inherited { get {...} set {...} }
        public virtual AttributeTargets ValidOn { get {...} }
    }

    public enum AttributeTargets
    {
        Assembly      = 0x0001,
        Module        = 0x0002,
        Class          = 0x0004,
        Struct         = 0x0008,
        Enum           = 0x0010,
        Constructor    = 0x0020,
        Method         = 0x0040,
        Property       = 0x0080,
        Field          = 0x0100,
        Event          = 0x0200,
        Interface      = 0x0400,
        Parameter      = 0x0800,
        Delegate       = 0x1000,
        ReturnValue    = 0x2000,

        All = Assembly | Module | Class | Struct | Enum | Constructor |
            Method | Property | Field | Event | Interface | Parameter |
            Delegate | ReturnValue
    }
}
```

The Conditional attribute

The attribute `Conditional` enables the definition of *conditional methods* and *conditional attribute classes*.

```

namespace System.Diagnostics
{
    [AttributeUsage(AttributeTargets.Method | AttributeTargets.Class, AllowMultiple = true)]
    public class ConditionalAttribute: Attribute
    {
        public ConditionalAttribute(string conditionString) {...}
        public string ConditionString { get {...} }
    }
}

```

Conditional methods

A method decorated with the `Conditional` attribute is a conditional method. The `Conditional` attribute indicates a condition by testing a conditional compilation symbol. Calls to a conditional method are either included or omitted depending on whether this symbol is defined at the point of the call. If the symbol is defined, the call is included; otherwise, the call (including evaluation of the receiver and parameters of the call) is omitted.

A conditional method is subject to the following restrictions:

- The conditional method must be a method in a *class_declaration* or *struct_declaration*. A compile-time error occurs if the `Conditional` attribute is specified on a method in an interface declaration.
- The conditional method must have a return type of `void`.
- The conditional method must not be marked with the `override` modifier. A conditional method may be marked with the `virtual` modifier, however. Overrides of such a method are implicitly conditional, and must not be explicitly marked with a `Conditional` attribute.
- The conditional method must not be an implementation of an interface method. Otherwise, a compile-time error occurs.

In addition, a compile-time error occurs if a conditional method is used in a *delegate_creation_expression*. The example

```

#define DEBUG

using System;
using System.Diagnostics;

class Class1
{
    [Conditional("DEBUG")]
    public static void M() {
        Console.WriteLine("Executed Class1.M");
    }
}

class Class2
{
    public static void Test() {
        Class1.M();
    }
}

```

declares `Class1.M` as a conditional method. `Class2`'s `Test` method calls this method. Since the conditional compilation symbol `DEBUG` is defined, if `Class2.Test` is called, it will call `M`. If the symbol `DEBUG` had not been defined, then `Class2.Test` would not call `Class1.M`.

It is important to note that the inclusion or exclusion of a call to a conditional method is controlled by the conditional compilation symbols at the point of the call. In the example

File `class1.cs` :

```
using System.Diagnostics;

class Class1
{
    [Conditional("DEBUG")]
    public static void F() {
        Console.WriteLine("Executed Class1.F");
    }
}
```

File `class2.cs` :

```
#define DEBUG

class Class2
{
    public static void G() {
        Class1.F();           // F is called
    }
}
```

File `class3.cs` :

```
#undef DEBUG

class Class3
{
    public static void H() {
        Class1.F();           // F is not called
    }
}
```

the classes `Class2` and `Class3` each contain calls to the conditional method `Class1.F`, which is conditional based on whether or not `DEBUG` is defined. Since this symbol is defined in the context of `Class2` but not `Class3`, the call to `F` in `Class2` is included, while the call to `F` in `Class3` is omitted.

The use of conditional methods in an inheritance chain can be confusing. Calls made to a conditional method through `base`, of the form `base.M`, are subject to the normal conditional method call rules. In the example

File `class1.cs` :

```
using System;
using System.Diagnostics;

class Class1
{
    [Conditional("DEBUG")]
    public virtual void M() {
        Console.WriteLine("Class1.M executed");
    }
}
```

File `class2.cs` :

```
using System;

class Class2: Class1
{
    public override void M() {
        Console.WriteLine("Class2.M executed");
        base.M();                // base.M is not called!
    }
}
```

File `class3.cs` :

```
#define DEBUG

using System;

class Class3
{
    public static void Test() {
        Class2 c = new Class2();
        c.M();                // M is called
    }
}
```

`Class2` includes a call to the `M` defined in its base class. This call is omitted because the base method is conditional based on the presence of the symbol `DEBUG`, which is undefined. Thus, the method writes to the console "`Class2.M executed`" only. Judicious use of *pp_declarations* can eliminate such problems.

Conditional attribute classes

An attribute class ([Attribute classes](#)) decorated with one or more `Conditional` attributes is a ***conditional attribute class***. A conditional attribute class is thus associated with the conditional compilation symbols declared in its `Conditional` attributes. This example:

```
using System;
using System.Diagnostics;
[Conditional("ALPHA")]
[Conditional("BETA")]
public class TestAttribute : Attribute {}
```

declares `TestAttribute` as a conditional attribute class associated with the conditional compilations symbols `ALPHA` and `BETA`.

Attribute specifications ([Attribute specification](#)) of a conditional attribute are included if one or more of its associated conditional compilation symbols is defined at the point of specification, otherwise the attribute specification is omitted.

It is important to note that the inclusion or exclusion of an attribute specification of a conditional attribute class is controlled by the conditional compilation symbols at the point of the specification. In the example

File `test.cs` :

```
using System;
using System.Diagnostics;

[Conditional("DEBUG")]

public class TestAttribute : Attribute {}
```

File `class1.cs` :

```
#define DEBUG

[Test]           // TestAttribute is specified

class Class1 {}
```

File `class2.cs` :

```
#undef DEBUG

[Test]           // TestAttribute is not specified

class Class2 {}
```

the classes `Class1` and `Class2` are each decorated with attribute `Test`, which is conditional based on whether or not `DEBUG` is defined. Since this symbol is defined in the context of `Class1` but not `Class2`, the specification of the `Test` attribute on `Class1` is included, while the specification of the `Test` attribute on `Class2` is omitted.

The Obsolete attribute

The attribute `Obsolete` is used to mark types and members of types that should no longer be used.

```
namespace System
{
    [AttributeUsage(
        AttributeTargets.Class |
        AttributeTargets.Struct |
        AttributeTargets.Enum |
        AttributeTargets.Interface |
        AttributeTargets.Delegate |
        AttributeTargets.Method |
        AttributeTargets.Constructor |
        AttributeTargets.Property |
        AttributeTargets.Field |
        AttributeTargets.Event,
        Inherited = false)
    ]
    public class ObsoleteAttribute: Attribute
    {
        public ObsoleteAttribute() {...}
        public ObsoleteAttribute(string message) {...}
        public ObsoleteAttribute(string message, bool error) {...}
        public string Message { get {...} }
        public bool IsError { get {...} }
    }
}
```

If a program uses a type or member that is decorated with the `Obsolete` attribute, the compiler issues a warning or an error. Specifically, the compiler issues a warning if no error parameter is provided, or if the error parameter is provided and has the value `false`. The compiler issues an error if the error parameter is specified and has the value `true`.

In the example

```
[Obsolete("This class is obsolete; use class B instead")]
class A
{
    public void F() {}
}

class B
{
    public void F() {}
}

class Test
{
    static void Main() {
        A a = new A();          // Warning
        a.F();
    }
}
```

the class `A` is decorated with the `Obsolete` attribute. Each use of `A` in `Main` results in a warning that includes the specified message, "This class is obsolete; use class B instead."

Caller info attributes

For purposes such as logging and reporting, it is sometimes useful for a function member to obtain certain compile-time information about the calling code. The caller info attributes provide a way to pass such information transparently.

When an optional parameter is annotated with one of the caller info attributes, omitting the corresponding argument in a call does not necessarily cause the default parameter value to be substituted. Instead, if the specified information about the calling context is available, that information will be passed as the argument value.

For example:

```
using System.Runtime.CompilerServices

...

public void Log(
    [CallerLineNumber] int line = -1,
    [CallerFilePath] string path = null,
    [CallerMemberName] string name = null
)
{
    Console.WriteLine((line < 0) ? "No line" : "Line " + line);
    Console.WriteLine((path == null) ? "No file path" : path);
    Console.WriteLine((name == null) ? "No member name" : name);
}
```

A call to `Log()` with no arguments would print the line number and file path of the call, as well as the name of the member within which the call occurred.

Caller info attributes can occur on optional parameters anywhere, including in delegate declarations. However, the specific caller info attributes have restrictions on the types of the parameters they can attribute, so that there will always be an implicit conversion from a substituted value to the parameter type.

It is an error to have the same caller info attribute on a parameter of both the defining and implementing part of a partial method declaration. Only caller info attributes in the defining part are applied, whereas caller info attributes occurring only in the implementing part are ignored.

Caller information does not affect overload resolution. As the attributed optional parameters are still omitted from the source code of the caller, overload resolution ignores those parameters in the same way it ignores other omitted optional parameters ([Overload resolution](#)).

Caller information is only substituted when a function is explicitly invoked in source code. Implicit invocations such as implicit parent constructor calls do not have a source location and will not substitute caller information. Also, calls that are dynamically bound will not substitute caller information. When a caller info attributed parameter is omitted in such cases, the specified default value of the parameter is used instead.

One exception is query-expressions. These are considered syntactic expansions, and if the calls they expand to omit optional parameters with caller info attributes, caller information will be substituted. The location used is the location of the query clause which the call was generated from.

If more than one caller info attribute is specified on a given parameter, they are preferred in the following order:

`CallerLineNumber`, `CallerFilePath`, `CallerMemberName`.

The `CallerLineNumber` attribute

The `System.Runtime.CompilerServices.CallerLineNumberAttribute` is allowed on optional parameters when there is a standard implicit conversion ([Standard implicit conversions](#)) from the constant value `int.MaxValue` to the parameter's type. This ensures that any non-negative line number up to that value can be passed without error.

If a function invocation from a location in source code omits an optional parameter with the `CallerLineNumberAttribute`, then a numeric literal representing that location's line number is used as an argument to the invocation instead of the default parameter value.

If the invocation spans multiple lines, the line chosen is implementation-dependent.

Note that the line number may be affected by `#line` directives ([Line directives](#)).

The `CallerFilePath` attribute

The `System.Runtime.CompilerServices.CallerFilePathAttribute` is allowed on optional parameters when there is a standard implicit conversion ([Standard implicit conversions](#)) from `string` to the parameter's type.

If a function invocation from a location in source code omits an optional parameter with the `CallerFilePathAttribute`, then a string literal representing that location's file path is used as an argument to the invocation instead of the default parameter value.

The format of the file path is implementation-dependent.

Note that the file path may be affected by `#line` directives ([Line directives](#)).

The `CallerMemberName` attribute

The `System.Runtime.CompilerServices.CallerMemberNameAttribute` is allowed on optional parameters when there is a standard implicit conversion ([Standard implicit conversions](#)) from `string` to the parameter's type.

If a function invocation from a location within the body of a function member or within an attribute applied to the function member itself or its return type, parameters or type parameters in source code omits an optional parameter with the `CallerMemberNameAttribute`, then a string literal representing the name of that member is used as an argument to the invocation instead of the default parameter value.

For invocations that occur within generic methods, only the method name itself is used, without the type parameter list.

For invocations that occur within explicit interface member implementations, only the method name itself is used, without the preceding interface qualification.

For invocations that occur within property or event accessors, the member name used is that of the property or event itself.

For invocations that occur within indexer accessors, the member name used is that supplied by an `IndexerNameAttribute` (The [IndexerName attribute](#)) on the indexer member, if present, or the default name `Item` otherwise.

For invocations that occur within declarations of instance constructors, static constructors, destructors and operators the member name used is implementation-dependent.

Attributes for Interoperation

Note: This section is applicable only to the Microsoft .NET implementation of C#.

Interoperation with COM and Win32 components

The .NET run-time provides a large number of attributes that enable C# programs to interoperate with components written using COM and Win32 DLLs. For example, the `DllImport` attribute can be used on a `static extern` method to indicate that the implementation of the method is to be found in a Win32 DLL. These attributes are found in the `System.Runtime.InteropServices` namespace, and detailed documentation for these attributes is found in the .NET runtime documentation.

Interoperation with other .NET languages

The `IndexerName` attribute

Indexers are implemented in .NET using indexed properties, and have a name in the .NET metadata. If no `IndexerName` attribute is present for an indexer, then the name `Item` is used by default. The `IndexerName` attribute enables a developer to override this default and specify a different name.

```
namespace System.Runtime.CompilerServices.CSharp
{
    [AttributeUsage(AttributeTargets.Property)]
    public class IndexerNameAttribute: Attribute
    {
        public IndexerNameAttribute(string indexerName) {...}
        public string Value { get {...} }
    }
}
```

Unsafe code

12/28/2021 • 39 minutes to read • [Edit Online](#)

The core C# language, as defined in the preceding chapters, differs notably from C and C++ in its omission of pointers as a data type. Instead, C# provides references and the ability to create objects that are managed by a garbage collector. This design, coupled with other features, makes C# a much safer language than C or C++. In the core C# language it is simply not possible to have an uninitialized variable, a "dangling" pointer, or an expression that indexes an array beyond its bounds. Whole categories of bugs that routinely plague C and C++ programs are thus eliminated.

While practically every pointer type construct in C or C++ has a reference type counterpart in C#, nonetheless, there are situations where access to pointer types becomes a necessity. For example, interfacing with the underlying operating system, accessing a memory-mapped device, or implementing a time-critical algorithm may not be possible or practical without access to pointers. To address this need, C# provides the ability to write *unsafe code*.

In unsafe code it is possible to declare and operate on pointers, to perform conversions between pointers and integral types, to take the address of variables, and so forth. In a sense, writing unsafe code is much like writing C code within a C# program.

Unsafe code is in fact a "safe" feature from the perspective of both developers and users. Unsafe code must be clearly marked with the modifier `unsafe`, so developers can't possibly use unsafe features accidentally, and the execution engine works to ensure that unsafe code cannot be executed in an untrusted environment.

Unsafe contexts

The unsafe features of C# are available only in unsafe contexts. An unsafe context is introduced by including an `unsafe` modifier in the declaration of a type or member, or by employing an *unsafe_statement*.

- A declaration of a class, struct, interface, or delegate may include an `unsafe` modifier, in which case the entire textual extent of that type declaration (including the body of the class, struct, or interface) is considered an unsafe context.
- A declaration of a field, method, property, event, indexer, operator, instance constructor, destructor, or static constructor may include an `unsafe` modifier, in which case the entire textual extent of that member declaration is considered an unsafe context.
- An *unsafe_statement* enables the use of an unsafe context within a *block*. The entire textual extent of the associated *block* is considered an unsafe context.

The associated grammar productions are shown below.

```

class_modifier_unsafe
    : 'unsafe'
    ;

struct_modifier_unsafe
    : 'unsafe'
    ;

interface_modifier_unsafe
    : 'unsafe'

    : unsafe_statement
    | fixed_statement
    ;

unsafe_statement
    : 'unsafe' block
    ;

```

In the example

```
public unsafe struct Node
{
    public int Value;
    public Node* Left;
    public Node* Right;
}
```

the `unsafe` modifier specified in the struct declaration causes the entire textual extent of the struct declaration to become an unsafe context. Thus, it is possible to declare the `Left` and `Right` fields to be of a pointer type. The example above could also be written

```
public struct Node
{
    public int Value;
    public unsafe Node* Left;
    public unsafe Node* Right;
}
```

Here, the `unsafe` modifiers in the field declarations cause those declarations to be considered unsafe contexts.

Other than establishing an unsafe context, thus permitting the use of pointer types, the `unsafe` modifier has no effect on a type or a member. In the example

```
public class A
{
    public unsafe virtual void F() {
        char* p;
        ...
    }
}

public class B: A
{
    public override void F() {
        base.F();
        ...
    }
}
```

the `unsafe` modifier on the `F` method in `A` simply causes the textual extent of `F` to become an unsafe context in which the unsafe features of the language can be used. In the override of `F` in `B`, there is no need to re-specify the `unsafe` modifier -- unless, of course, the `F` method in `B` itself needs access to unsafe features.

The situation is slightly different when a pointer type is part of the method's signature

```
public unsafe class A
{
    public virtual void F(char* p) {...}
}

public class B: A
{
    public unsafe override void F(char* p) {...}
}
```

Here, because `F`'s signature includes a pointer type, it can only be written in an unsafe context. However, the unsafe context can be introduced by either making the entire class unsafe, as is the case in `A`, or by including an

`unsafe` modifier in the method declaration, as is the case in `B`.

Pointer types

In an unsafe context, a *type* ([Types](#)) may be a *pointer_type* as well as a *value_type* or a *reference_type*. However, a *pointer_type* may also be used in a `typeof` expression ([Anonymous object creation expressions](#)) outside of an unsafe context as such usage is not unsafe.

```
type_unsafe
    : pointer_type
    ;
```

A *pointer_type* is written as an *unmanaged_type* or the keyword `void`, followed by a `*` token:

```
pointer_type
    : unmanaged_type '*'
    | 'void' '*'
    ;

unmanaged_type
    : type
    ;
```

The type specified before the `*` in a pointer type is called the *referent type* of the pointer type. It represents the type of the variable to which a value of the pointer type points.

Unlike references (values of reference types), pointers are not tracked by the garbage collector -- the garbage collector has no knowledge of pointers and the data to which they point. For this reason a pointer is not permitted to point to a reference or to a struct that contains references, and the referent type of a pointer must be an *unmanaged_type*.

An *unmanaged_type* is any type that isn't a *reference_type* or constructed type, and doesn't contain *reference_type* or constructed type fields at any level of nesting. In other words, an *unmanaged_type* is one of the following:

- `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `long`, `ulong`, `char`, `float`, `double`, `decimal`, Or `bool`.
- Any *enum_type*.
- Any *pointer_type*.
- Any user-defined *struct_type* that is not a constructed type and contains fields of *unmanaged_types* only.

The intuitive rule for mixing of pointers and references is that referents of references (objects) are permitted to contain pointers, but referents of pointers are not permitted to contain references.

Some examples of pointer types are given in the table below:

EXAMPLE	DESCRIPTION
<code>byte*</code>	Pointer to <code>byte</code>
<code>char*</code>	Pointer to <code>char</code>
<code>int**</code>	Pointer to pointer to <code>int</code>
<code>int*[]</code>	Single-dimensional array of pointers to <code>int</code>

EXAMPLE	DESCRIPTION
<code>void*</code>	Pointer to unknown type

For a given implementation, all pointer types must have the same size and representation.

Unlike C and C++, when multiple pointers are declared in the same declaration, in C# the `*` is written along with the underlying type only, not as a prefix punctuator on each pointer name. For example

```
int* pi, pj;    // NOT as int *pi, *pj;
```

The value of a pointer having type `T*` represents the address of a variable of type `T`. The pointer indirection operator `*` ([Pointer indirection](#)) may be used to access this variable. For example, given a variable `p` of type `int*`, the expression `*p` denotes the `int` variable found at the address contained in `p`.

Like an object reference, a pointer may be `null`. Applying the indirection operator to a `null` pointer results in implementation-defined behavior. A pointer with value `null` is represented by all-bits-zero.

The `void*` type represents a pointer to an unknown type. Because the referent type is unknown, the indirection operator cannot be applied to a pointer of type `void*`, nor can any arithmetic be performed on such a pointer. However, a pointer of type `void*` can be cast to any other pointer type (and vice versa).

Pointer types are a separate category of types. Unlike reference types and value types, pointer types do not inherit from `object` and no conversions exist between pointer types and `object`. In particular, boxing and unboxing ([Boxing and unboxing](#)) are not supported for pointers. However, conversions are permitted between different pointer types and between pointer types and the integral types. This is described in [Pointer conversions](#).

A *pointer_type* cannot be used as a type argument ([Constructed types](#)), and type inference ([Type inference](#)) fails on generic method calls that would have inferred a type argument to be a pointer type.

A *pointer_type* may be used as the type of a volatile field ([Volatile fields](#)).

Although pointers can be passed as `ref` or `out` parameters, doing so can cause undefined behavior, since the pointer may well be set to point to a local variable which no longer exists when the called method returns, or the fixed object to which it used to point, is no longer fixed. For example:

```

using System;

class Test
{
    static int value = 20;

    unsafe static void F(out int* pi1, ref int* pi2) {
        int i = 10;
        pi1 = &i;

        fixed (int* pj = &value) {
            // ...
            pi2 = pj;
        }
    }

    static void Main() {
        int i = 10;
        unsafe {
            int* px1;
            int* px2 = &i;

            F(out px1, ref px2);

            Console.WriteLine("*px1 = {0}, *px2 = {1}",
                              *px1, *px2);    // undefined behavior
        }
    }
}

```

A method can return a value of some type, and that type can be a pointer. For example, when given a pointer to a contiguous sequence of `int` s, that sequence's element count, and some other `int` value, the following method returns the address of that value in that sequence, if a match occurs; otherwise it returns `null` :

```

unsafe static int* Find(int* pi, int size, int value) {
    for (int i = 0; i < size; ++i) {
        if (*pi == value)
            return pi;
        ++pi;
    }
    return null;
}

```

In an unsafe context, several constructs are available for operating on pointers:

- The `*` operator may be used to perform pointer indirection ([Pointer indirection](#)).
- The `->` operator may be used to access a member of a struct through a pointer ([Pointer member access](#)).
- The `[]` operator may be used to index a pointer ([Pointer element access](#)).
- The `&` operator may be used to obtain the address of a variable ([The address-of operator](#)).
- The `++` and `--` operators may be used to increment and decrement pointers ([Pointer increment and decrement](#)).
- The `+` and `-` operators may be used to perform pointer arithmetic ([Pointer arithmetic](#)).
- The `==`, `!=`, `<`, `>`, `<=`, and `>=` operators may be used to compare pointers ([Pointer comparison](#)).
- The `stackalloc` operator may be used to allocate memory from the call stack ([Fixed size buffers](#)).
- The `fixed` statement may be used to temporarily fix a variable so its address can be obtained ([The fixed statement](#)).

Fixed and moveable variables

The address-of operator ([The address-of operator](#)) and the `fixed` statement ([The fixed statement](#)) divide variables into two categories: *Fixed variables* and *moveable variables*.

Fixed variables reside in storage locations that are unaffected by operation of the garbage collector. (Examples of fixed variables include local variables, value parameters, and variables created by dereferencing pointers.) On the other hand, moveable variables reside in storage locations that are subject to relocation or disposal by the garbage collector. (Examples of moveable variables include fields in objects and elements of arrays.)

The `&` operator ([The address-of operator](#)) permits the address of a fixed variable to be obtained without restrictions. However, because a moveable variable is subject to relocation or disposal by the garbage collector, the address of a moveable variable can only be obtained using a `fixed` statement ([The fixed statement](#)), and that address remains valid only for the duration of that `fixed` statement.

In precise terms, a fixed variable is one of the following:

- A variable resulting from a *simple_name* ([Simple names](#)) that refers to a local variable or a value parameter, unless the variable is captured by an anonymous function.
- A variable resulting from a *member_access* ([Member access](#)) of the form `v.I`, where `v` is a fixed variable of a *struct_type*.
- A variable resulting from a *pointer_indirection_expression* ([Pointer indirection](#)) of the form `*p`, a *pointer_member_access* ([Pointer member access](#)) of the form `p->I`, or a *pointer_element_access* ([Pointer element access](#)) of the form `p[E]`.

All other variables are classified as moveable variables.

Note that a static field is classified as a moveable variable. Also note that a `ref` or `out` parameter is classified as a moveable variable, even if the argument given for the parameter is a fixed variable. Finally, note that a variable produced by dereferencing a pointer is always classified as a fixed variable.

Pointer conversions

In an unsafe context, the set of available implicit conversions ([Implicit conversions](#)) is extended to include the following implicit pointer conversions:

- From any *pointer_type* to the type `void*`.
- From the `null` literal to any *pointer_type*.

Additionally, in an unsafe context, the set of available explicit conversions ([Explicit conversions](#)) is extended to include the following explicit pointer conversions:

- From any *pointer_type* to any other *pointer_type*.
- From `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `long`, or `ulong` to any *pointer_type*.
- From any *pointer_type* to `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `long`, or `ulong`.

Finally, in an unsafe context, the set of standard implicit conversions ([Standard implicit conversions](#)) includes the following pointer conversion:

- From any *pointer_type* to the type `void*`.

Conversions between two pointer types never change the actual pointer value. In other words, a conversion from one pointer type to another has no effect on the underlying address given by the pointer.

When one pointer type is converted to another, if the resulting pointer is not correctly aligned for the pointed-to type, the behavior is undefined if the result is dereferenced. In general, the concept "correctly aligned" is transitive: if a pointer to type `A` is correctly aligned for a pointer to type `B`, which, in turn, is correctly aligned for a pointer to type `C`, then a pointer to type `A` is correctly aligned for a pointer to type `C`.

Consider the following case in which a variable having one type is accessed via a pointer to a different type:

```
char c = 'A';
char* pc = &c;
void* pv = pc;
int* pi = (int*)pv;
int i = *pi;          // undefined
*pi = 123456;         // undefined
```

When a pointer type is converted to a pointer to byte, the result points to the lowest addressed byte of the variable. Successive increments of the result, up to the size of the variable, yield pointers to the remaining bytes of that variable. For example, the following method displays each of the eight bytes in a double as a hexadecimal value:

```
using System;

class Test
{
    unsafe static void Main() {
        double d = 123.456e23;
        unsafe {
            byte* pb = (byte*)&d;
            for (int i = 0; i < sizeof(double); ++i)
                Console.WriteLine("{0:X2} ", *pb++);
        }
    }
}
```

Of course, the output produced depends on endianness.

Mappings between pointers and integers are implementation-defined. However, on 32* and 64-bit CPU architectures with a linear address space, conversions of pointers to or from integral types typically behave exactly like conversions of `uint` or `ulong` values, respectively, to or from those integral types.

Pointer arrays

In an unsafe context, arrays of pointers can be constructed. Only some of the conversions that apply to other array types are allowed on pointer arrays:

- The implicit reference conversion ([Implicit reference conversions](#)) from any *array_type* to `System.Array` and the interfaces it implements also applies to pointer arrays. However, any attempt to access the array elements through `System.Array` or the interfaces it implements will result in an exception at run-time, as pointer types are not convertible to `object`.
- The implicit and explicit reference conversions ([Implicit reference conversions](#), [Explicit reference conversions](#)) from a single-dimensional array type `S[]` to `System.Collections.Generic.IList<T>` and its generic base interfaces never apply to pointer arrays, since pointer types cannot be used as type arguments, and there are no conversions from pointer types to non-pointer types.
- The explicit reference conversion ([Explicit reference conversions](#)) from `System.Array` and the interfaces it implements to any *array_type* applies to pointer arrays.
- The explicit reference conversions ([Explicit reference conversions](#)) from `System.Collections.Generic.IList<S>` and its base interfaces to a single-dimensional array type `T[]` never applies to pointer arrays, since pointer types cannot be used as type arguments, and there are no conversions from pointer types to non-pointer types.

These restrictions mean that the expansion for the `foreach` statement over arrays described in [The foreach statement](#) cannot be applied to pointer arrays. Instead, a `foreach` statement of the form

```
foreach (V v in x) embedded_statement
```

where the type of `x` is an array type of the form `T[,,...,]`, `N` is the number of dimensions minus 1 and `T` or `V` is a pointer type, is expanded using nested for-loops as follows:

```
{
    T[,,...,] a = x;
    for (int i0 = a.GetLowerBound(0); i0 <= a.GetUpperBound(0); i0++)
    for (int i1 = a.GetLowerBound(1); i1 <= a.GetUpperBound(1); i1++)
    ...
    for (int iN = a.GetLowerBound(N); iN <= a.GetUpperBound(N); iN++) {
        V v = (V)a.GetValue(i0,i1,...,iN);
        embedded_statement
    }
}
```

The variables `a`, `i0`, `i1`, ..., `iN` are not visible to or accessible to `x` or the *embedded_statement* or any other source code of the program. The variable `v` is read-only in the embedded statement. If there is not an explicit conversion ([Pointer conversions](#)) from `T` (the element type) to `V`, an error is produced and no further steps are taken. If `x` has the value `null`, a `System.NullReferenceException` is thrown at run-time.

Pointers in expressions

In an unsafe context, an expression may yield a result of a pointer type, but outside an unsafe context it is a compile-time error for an expression to be of a pointer type. In precise terms, outside an unsafe context a compile-time error occurs if any *simple_name* ([Simple names](#)), *member_access* ([Member access](#)), *invocation_expression* ([Invocation expressions](#)), or *element_access* ([Element access](#)) is of a pointer type.

In an unsafe context, the *primary_no_array_creation_expression* ([Primary expressions](#)) and *unary_expression* ([Unary operators](#)) productions permit the following additional constructs:

```
primary_no_array_creation_expression_unsafe
: pointer_member_access
| pointer_element_access
| sizeof_expression
;

unary_expression_unsafe
: pointer_indirection_expression
| addressof_expression
;
```

These constructs are described in the following sections. The precedence and associativity of the unsafe operators is implied by the grammar.

Pointer indirection

A *pointer_indirection_expression* consists of an asterisk (`*`) followed by a *unary_expression*.

```
pointer_indirection_expression
: '*' unary_expression
;
```

The unary `*` operator denotes pointer indirection and is used to obtain the variable to which a pointer points. The result of evaluating `*P`, where `P` is an expression of a pointer type `T*`, is a variable of type `T`. It is a compile-time error to apply the unary `*` operator to an expression of type `void*` or to an expression that isn't

of a pointer type.

The effect of applying the unary `*` operator to a `null` pointer is implementation-defined. In particular, there is no guarantee that this operation throws a `System.NullReferenceException`.

If an invalid value has been assigned to the pointer, the behavior of the unary `*` operator is undefined. Among the invalid values for dereferencing a pointer by the unary `*` operator are an address inappropriately aligned for the type pointed to (see example in [Pointer conversions](#)), and the address of a variable after the end of its lifetime.

For purposes of definite assignment analysis, a variable produced by evaluating an expression of the form `*P` is considered initially assigned ([Initially assigned variables](#)).

Pointer member access

A *pointer_member_access* consists of a *primary_expression*, followed by a `->` token, followed by an *identifier* and an optional *type_argument_list*.

```
pointer_member_access
    : primary_expression '->' identifier
    ;
```

In a pointer member access of the form `P->I`, `P` must be an expression of a pointer type other than `void*`, and `I` must denote an accessible member of the type to which `P` points.

A pointer member access of the form `P->I` is evaluated exactly as `(*P).I`. For a description of the pointer indirection operator (`*`), see [Pointer indirection](#). For a description of the member access operator (`.`), see [Member access](#).

In the example

```
using System;

struct Point
{
    public int x;
    public int y;

    public override string ToString() {
        return "(" + x + "," + y + ")";
    }
}

class Test
{
    static void Main() {
        Point point;
        unsafe {
            Point* p = &point;
            p->x = 10;
            p->y = 20;
            Console.WriteLine(p->ToString());
        }
    }
}
```

the `->` operator is used to access fields and invoke a method of a struct through a pointer. Because the operation `P->I` is precisely equivalent to `(*P).I`, the `Main` method could equally well have been written:

```

class Test
{
    static void Main() {
        Point point;
        unsafe {
            Point* p = &point;
            (*p).x = 10;
            (*p).y = 20;
            Console.WriteLine((*p).ToString());
        }
    }
}

```

Pointer element access

A *pointer_element_access* consists of a *primary_no_array_creation_expression* followed by an expression enclosed in "[" and "]".

```

pointer_element_access
: primary_no_array_creation_expression '[' expression ']'
;

```

In a pointer element access of the form `P[E]`, `P` must be an expression of a pointer type other than `void*`, and `E` must be an expression that can be implicitly converted to `int`, `uint`, `long`, or `ulong`.

A pointer element access of the form `P[E]` is evaluated exactly as `*(P + E)`. For a description of the pointer indirection operator (`*`), see [Pointer indirection](#). For a description of the pointer addition operator (`+`), see [Pointer arithmetic](#).

In the example

```

class Test
{
    static void Main() {
        unsafe {
            char* p = stackalloc char[256];
            for (int i = 0; i < 256; i++) p[i] = (char)i;
        }
    }
}

```

a pointer element access is used to initialize the character buffer in a `for` loop. Because the operation `P[E]` is precisely equivalent to `*(P + E)`, the example could equally well have been written:

```

class Test
{
    static void Main() {
        unsafe {
            char* p = stackalloc char[256];
            for (int i = 0; i < 256; i++) *(p + i) = (char)i;
        }
    }
}

```

The pointer element access operator does not check for out-of-bounds errors and the behavior when accessing an out-of-bounds element is undefined. This is the same as C and C++.

The address-of operator

An *addressof_expression* consists of an ampersand (`&`) followed by a *unary_expression*.

```
addressof_expression
: '&' unary_expression
;
```

Given an expression `E` which is of a type `T` and is classified as a fixed variable ([Fixed and moveable variables](#)), the construct `&E` computes the address of the variable given by `E`. The type of the result is `T*` and is classified as a value. A compile-time error occurs if `E` is not classified as a variable, if `E` is classified as a read-only local variable, or if `E` denotes a moveable variable. In the last case, a fixed statement ([The fixed statement](#)) can be used to temporarily "fix" the variable before obtaining its address. As stated in [Member access](#), outside an instance constructor or static constructor for a struct or class that defines a `readonly` field, that field is considered a value, not a variable. As such, its address cannot be taken. Similarly, the address of a constant cannot be taken.

The `&` operator does not require its argument to be definitely assigned, but following an `&` operation, the variable to which the operator is applied is considered definitely assigned in the execution path in which the operation occurs. It is the responsibility of the programmer to ensure that correct initialization of the variable actually does take place in this situation.

In the example

```
using System;

class Test
{
    static void Main() {
        int i;
        unsafe {
            int* p = &i;
            *p = 123;
        }
        Console.WriteLine(i);
    }
}
```

`i` is considered definitely assigned following the `&i` operation used to initialize `p`. The assignment to `*p` in effect initializes `i`, but the inclusion of this initialization is the responsibility of the programmer, and no compile-time error would occur if the assignment was removed.

The rules of definite assignment for the `&` operator exist such that redundant initialization of local variables can be avoided. For example, many external APIs take a pointer to a structure which is filled in by the API. Calls to such APIs typically pass the address of a local struct variable, and without the rule, redundant initialization of the struct variable would be required.

Pointer increment and decrement

In an unsafe context, the `++` and `--` operators ([Postfix increment and decrement operators](#) and [Prefix increment and decrement operators](#)) can be applied to pointer variables of all types except `void*`. Thus, for every pointer type `T*`, the following operators are implicitly defined:

```
T* operator ++(T* x);
T* operator --(T* x);
```

The operators produce the same results as `x + 1` and `x - 1`, respectively ([Pointer arithmetic](#)). In other words, for a pointer variable of type `T*`, the `++` operator adds `sizeof(T)` to the address contained in the variable, and

the `--` operator subtracts `sizeof(T)` from the address contained in the variable.

If a pointer increment or decrement operation overflows the domain of the pointer type, the result is implementation-defined, but no exceptions are produced.

Pointer arithmetic

In an unsafe context, the `+` and `-` operators ([Addition operator](#) and [Subtraction operator](#)) can be applied to values of all pointer types except `void*`. Thus, for every pointer type `T*`, the following operators are implicitly defined:

```
T* operator +(T* x, int y);
T* operator +(T* x, uint y);
T* operator +(T* x, long y);
T* operator +(T* x, ulong y);

T* operator +(int x, T* y);
T* operator +(uint x, T* y);
T* operator +(long x, T* y);
T* operator +(ulong x, T* y);

T* operator -(T* x, int y);
T* operator -(T* x, uint y);
T* operator -(T* x, long y);
T* operator -(T* x, ulong y);

long operator -(T* x, T* y);
```

Given an expression `P` of a pointer type `T*` and an expression `N` of type `int`, `uint`, `long`, or `ulong`, the expressions `P + N` and `N + P` compute the pointer value of type `T*` that results from adding `N * sizeof(T)` to the address given by `P`. Likewise, the expression `P - N` computes the pointer value of type `T*` that results from subtracting `N * sizeof(T)` from the address given by `P`.

Given two expressions, `P` and `Q`, of a pointer type `T*`, the expression `P - Q` computes the difference between the addresses given by `P` and `Q` and then divides that difference by `sizeof(T)`. The type of the result is always `long`. In effect, `P - Q` is computed as `((long)(P) - (long)(Q)) / sizeof(T)`.

For example:

```
using System;

class Test
{
    static void Main() {
        unsafe {
            int* values = stackalloc int[20];
            int* p = &values[1];
            int* q = &values[15];
            Console.WriteLine("p - q = {0}", p - q);
            Console.WriteLine("q - p = {0}", q - p);
        }
    }
}
```

which produces the output:

```
p - q = -14
q - p = 14
```

If a pointer arithmetic operation overflows the domain of the pointer type, the result is truncated in an

implementation-defined fashion, but no exceptions are produced.

Pointer comparison

In an unsafe context, the `==`, `!=`, `<`, `>`, `<=`, and `>=` operators ([Relational and type-testing operators](#)) can be applied to values of all pointer types. The pointer comparison operators are:

```
bool operator ==(void* x, void* y);
bool operator !=(void* x, void* y);
bool operator <(void* x, void* y);
bool operator >(void* x, void* y);
bool operator <=(void* x, void* y);
bool operator >=(void* x, void* y);
```

Because an implicit conversion exists from any pointer type to the `void*` type, operands of any pointer type can be compared using these operators. The comparison operators compare the addresses given by the two operands as if they were unsigned integers.

The sizeof operator

The `sizeof` operator returns the number of bytes occupied by a variable of a given type. The type specified as an operand to `sizeof` must be an *unmanaged_type* ([Pointer types](#)).

```
sizeof_expression
: 'sizeof' '(' unmanaged_type ')'
;
```

The result of the `sizeof` operator is a value of type `int`. For certain predefined types, the `sizeof` operator yields a constant value as shown in the table below.

EXPRESSION	RESULT
<code>sizeof(sbyte)</code>	1
<code>sizeof(byte)</code>	1
<code>sizeof(short)</code>	2
<code>sizeof(ushort)</code>	2
<code>sizeof(int)</code>	4
<code>sizeof(uint)</code>	4
<code>sizeof(long)</code>	8
<code>sizeof(ulong)</code>	8
<code>sizeof(char)</code>	2
<code>sizeof(float)</code>	4
<code>sizeof(double)</code>	8

EXPRESSION	RESULT
<code>sizeof(bool)</code>	1

For all other types, the result of the `sizeof` operator is implementation-defined and is classified as a value, not a constant.

The order in which members are packed into a struct is unspecified.

For alignment purposes, there may be unnamed padding at the beginning of a struct, within a struct, and at the end of the struct. The contents of the bits used as padding are indeterminate.

When applied to an operand that has struct type, the result is the total number of bytes in a variable of that type, including any padding.

The fixed statement

In an unsafe context, the *embedded_statement* ([Statements](#)) production permits an additional construct, the `fixed` statement, which is used to "fix" a moveable variable such that its address remains constant for the duration of the statement.

```

fixed_statement
: 'fixed' '(' pointer_type fixed_pointer_declarators ')' embedded_statement
;

fixed_pointer_declarators
: fixed_pointer_declarator (',' fixed_pointer_declarator)*
;

fixed_pointer_declarator
: identifier '=' fixed_pointer_initializer
;

fixed_pointer_initializer
: '&' variable_reference
| expression
;

```

Each *fixed_pointer_declarator* declares a local variable of the given *pointer_type* and initializes that local variable with the address computed by the corresponding *fixed_pointer_initializer*. A local variable declared in a `fixed` statement is accessible in any *fixed_pointer_initializers* occurring to the right of that variable's declaration, and in the *embedded_statement* of the `fixed` statement. A local variable declared by a `fixed` statement is considered read-only. A compile-time error occurs if the embedded statement attempts to modify this local variable (via assignment or the `++` and `--` operators) or pass it as a `ref` or `out` parameter.

A *fixed_pointer_initializer* can be one of the following:

- The token `"&"` followed by a *variable_reference* ([Precise rules for determining definite assignment](#)) to a moveable variable ([Fixed and moveable variables](#)) of an unmanaged type `T`, provided the type `T*` is implicitly convertible to the pointer type given in the `fixed` statement. In this case, the initializer computes the address of the given variable, and the variable is guaranteed to remain at a fixed address for the duration of the `fixed` statement.
- An expression of an *array_type* with elements of an unmanaged type `T`, provided the type `T*` is implicitly convertible to the pointer type given in the `fixed` statement. In this case, the initializer computes the address of the first element in the array, and the entire array is guaranteed to remain at a fixed address for the duration of the `fixed` statement. If the array expression is null or if the array has zero elements, the initializer computes an address equal to zero.

- An expression of type `string`, provided the type `char*` is implicitly convertible to the pointer type given in the `fixed` statement. In this case, the initializer computes the address of the first character in the string, and the entire string is guaranteed to remain at a fixed address for the duration of the `fixed` statement. The behavior of the `fixed` statement is implementation-defined if the string expression is null.
- A *simple_name* or *member_access* that references a fixed size buffer member of a moveable variable, provided the type of the fixed size buffer member is implicitly convertible to the pointer type given in the `fixed` statement. In this case, the initializer computes a pointer to the first element of the fixed size buffer ([Fixed size buffers in expressions](#)), and the fixed size buffer is guaranteed to remain at a fixed address for the duration of the `fixed` statement.

For each address computed by a *fixed_pointer_initializer* the `fixed` statement ensures that the variable referenced by the address is not subject to relocation or disposal by the garbage collector for the duration of the `fixed` statement. For example, if the address computed by a *fixed_pointer_initializer* references a field of an object or an element of an array instance, the `fixed` statement guarantees that the containing object instance is not relocated or disposed of during the lifetime of the statement.

It is the programmer's responsibility to ensure that pointers created by `fixed` statements do not survive beyond execution of those statements. For example, when pointers created by `fixed` statements are passed to external APIs, it is the programmer's responsibility to ensure that the APIs retain no memory of these pointers.

Fixed objects may cause fragmentation of the heap (because they can't be moved). For that reason, objects should be fixed only when absolutely necessary and then only for the shortest amount of time possible.

The example

```
class Test
{
    static int x;
    int y;

    unsafe static void F(int* p) {
        *p = 1;
    }

    static void Main() {
        Test t = new Test();
        int[] a = new int[10];
        unsafe {
            fixed (int* p = &x) F(p);
            fixed (int* p = &t.y) F(p);
            fixed (int* p = &a[0]) F(p);
            fixed (int* p = a) F(p);
        }
    }
}
```

demonstrates several uses of the `fixed` statement. The first statement fixes and obtains the address of a static field, the second statement fixes and obtains the address of an instance field, and the third statement fixes and obtains the address of an array element. In each case it would have been an error to use the regular `&` operator since the variables are all classified as moveable variables.

The fourth `fixed` statement in the example above produces a similar result to the third.

This example of the `fixed` statement uses `string`:

```

class Test
{
    static string name = "xx";

    unsafe static void F(char* p) {
        for (int i = 0; p[i] != '\0'; ++i)
            Console.WriteLine(p[i]);
    }

    static void Main() {
        unsafe {
            fixed (char* p = name) F(p);
            fixed (char* p = "xx") F(p);
        }
    }
}

```

In an unsafe context array elements of single-dimensional arrays are stored in increasing index order, starting with index `0` and ending with index `Length - 1`. For multi-dimensional arrays, array elements are stored such that the indices of the rightmost dimension are increased first, then the next left dimension, and so on to the left. Within a `fixed` statement that obtains a pointer `p` to an array instance `a`, the pointer values ranging from `p` to `p + a.Length - 1` represent addresses of the elements in the array. Likewise, the variables ranging from `p[0]` to `p[a.Length - 1]` represent the actual array elements. Given the way in which arrays are stored, we can treat an array of any dimension as though it were linear.

For example:

```

using System;

class Test
{
    static void Main() {
        int[, ,] a = new int[2,3,4];
        unsafe {
            fixed (int* p = a) {
                for (int i = 0; i < a.Length; ++i)    // treat as linear
                    p[i] = i;
            }
        }

        for (int i = 0; i < 2; ++i)
            for (int j = 0; j < 3; ++j) {
                for (int k = 0; k < 4; ++k)
                    Console.Write("{0},{1},{2}] = {3,2} ", i, j, k, a[i,j,k]);
                Console.WriteLine();
            }
    }
}

```

which produces the output:

```

[0,0,0] = 0 [0,0,1] = 1 [0,0,2] = 2 [0,0,3] = 3
[0,1,0] = 4 [0,1,1] = 5 [0,1,2] = 6 [0,1,3] = 7
[0,2,0] = 8 [0,2,1] = 9 [0,2,2] = 10 [0,2,3] = 11
[1,0,0] = 12 [1,0,1] = 13 [1,0,2] = 14 [1,0,3] = 15
[1,1,0] = 16 [1,1,1] = 17 [1,1,2] = 18 [1,1,3] = 19
[1,2,0] = 20 [1,2,1] = 21 [1,2,2] = 22 [1,2,3] = 23

```

In the example

```

class Test
{
    unsafe static void Fill(int* p, int count, int value) {
        for (; count != 0; count--) *p++ = value;
    }

    static void Main() {
        int[] a = new int[100];
        unsafe {
            fixed (int* p = a) Fill(p, 100, -1);
        }
    }
}

```

a `fixed` statement is used to fix an array so its address can be passed to a method that takes a pointer.

In the example:

```

unsafe struct Font
{
    public int size;
    public fixed char name[32];
}

class Test
{
    unsafe static void PutString(string s, char* buffer, int bufSize) {
        int len = s.Length;
        if (len > bufSize) len = bufSize;
        for (int i = 0; i < len; i++) buffer[i] = s[i];
        for (int i = len; i < bufSize; i++) buffer[i] = (char)0;
    }

    Font f;

    unsafe static void Main()
    {
        Test test = new Test();
        test.f.size = 10;
        fixed (char* p = test.f.name) {
            PutString("Times New Roman", p, 32);
        }
    }
}

```

a `fixed` statement is used to fix a fixed size buffer of a struct so its address can be used as a pointer.

A `char*` value produced by fixing a string instance always points to a null-terminated string. Within a `fixed` statement that obtains a pointer `p` to a string instance `s`, the pointer values ranging from `p` to `p + s.Length - 1` represent addresses of the characters in the string, and the pointer value `p + s.Length` always points to a null character (the character with value `'\0'`).

Modifying objects of managed type through fixed pointers can result in undefined behavior. For example, because strings are immutable, it is the programmer's responsibility to ensure that the characters referenced by a pointer to a fixed string are not modified.

The automatic null-termination of strings is particularly convenient when calling external APIs that expect "C-style" strings. Note, however, that a string instance is permitted to contain null characters. If such null characters are present, the string will appear truncated when treated as a null-terminated `char*`.

Fixed size buffers

Fixed size buffers are used to declare "C style" in-line arrays as members of structs, and are primarily useful for interfacing with unmanaged APIs.

Fixed size buffer declarations

A *fixed size buffer* is a member that represents storage for a fixed length buffer of variables of a given type. A fixed size buffer declaration introduces one or more fixed size buffers of a given element type. Fixed size buffers are only permitted in struct declarations and can only occur in unsafe contexts ([Unsafe contexts](#)).

```
struct_member_declaration_unsafe
: fixed_size_buffer_declaration
;

fixed_size_buffer_declaration
: attributes? fixed_size_buffer_modifier* 'fixed' buffer_element_type fixed_size_buffer_declarator+ ';'
;

fixed_size_buffer_modifier
: 'new'
| 'public'
| 'protected'
| 'internal'
| 'private'
| 'unsafe'
;

buffer_element_type
: type
;

fixed_size_buffer_declarator
: identifier '[' constant_expression ']'
;
```

A fixed size buffer declaration may include a set of attributes ([Attributes](#)), a `new` modifier ([Modifiers](#)), a valid combination of the four access modifiers ([Type parameters and constraints](#)) and an `unsafe` modifier ([Unsafe contexts](#)). The attributes and modifiers apply to all of the members declared by the fixed size buffer declaration. It is an error for the same modifier to appear multiple times in a fixed size buffer declaration.

A fixed size buffer declaration is not permitted to include the `static` modifier.

The buffer element type of a fixed size buffer declaration specifies the element type of the buffer(s) introduced by the declaration. The buffer element type must be one of the predefined types `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `long`, `ulong`, `char`, `float`, `double`, or `bool`.

The buffer element type is followed by a list of fixed size buffer declarators, each of which introduces a new member. A fixed size buffer declarator consists of an identifier that names the member, followed by a constant expression enclosed in `[` and `]` tokens. The constant expression denotes the number of elements in the member introduced by that fixed size buffer declarator. The type of the constant expression must be implicitly convertible to type `int`, and the value must be a non-zero positive integer.

The elements of a fixed size buffer are guaranteed to be laid out sequentially in memory.

A fixed size buffer declaration that declares multiple fixed size buffers is equivalent to multiple declarations of a single fixed size buffer declaration with the same attributes, and element types. For example

```
unsafe struct A
{
    public fixed int x[5], y[10], z[100];
}
```

is equivalent to

```
unsafe struct A
{
    public fixed int x[5];
    public fixed int y[10];
    public fixed int z[100];
}
```

Fixed size buffers in expressions

Member lookup ([Operators](#)) of a fixed size buffer member proceeds exactly like member lookup of a field.

A fixed size buffer can be referenced in an expression using a *simple_name* ([Type inference](#)) or a *member_access* ([Compile-time checking of dynamic overload resolution](#)).

When a fixed size buffer member is referenced as a simple name, the effect is the same as a member access of the form `this.I`, where `I` is the fixed size buffer member.

In a member access of the form `E.I`, if `E` is of a struct type and a member lookup of `I` in that struct type identifies a fixed size member, then `E.I` is evaluated and classified as follows:

- If the expression `E.I` does not occur in an unsafe context, a compile-time error occurs.
- If `E` is classified as a value, a compile-time error occurs.
- Otherwise, if `E` is a moveable variable ([Fixed and moveable variables](#)) and the expression `E.I` is not a *fixed_pointer_initializer* ([The fixed statement](#)), a compile-time error occurs.
- Otherwise, `E` references a fixed variable and the result of the expression is a pointer to the first element of the fixed size buffer member `I` in `E`. The result is of type `S*`, where `S` is the element type of `I`, and is classified as a value.

The subsequent elements of the fixed size buffer can be accessed using pointer operations from the first element. Unlike access to arrays, access to the elements of a fixed size buffer is an unsafe operation and is not range checked.

The following example declares and uses a struct with a fixed size buffer member.

```
unsafe struct Font
{
    public int size;
    public fixed char name[32];
}

class Test
{
    unsafe static void PutString(string s, char* buffer, int bufSize) {
        int len = s.Length;
        if (len > bufSize) len = bufSize;
        for (int i = 0; i < len; i++) buffer[i] = s[i];
        for (int i = len; i < bufSize; i++) buffer[i] = (char)0;
    }

    unsafe static void Main()
    {
        Font f;
        f.size = 10;
        PutString("Times New Roman", f.name, 32);
    }
}
```

Definite assignment checking

Fixed size buffers are not subject to definite assignment checking ([Definite assignment](#)), and fixed size buffer members are ignored for purposes of definite assignment checking of struct type variables.

When the outermost containing struct variable of a fixed size buffer member is a static variable, an instance variable of a class instance, or an array element, the elements of the fixed size buffer are automatically initialized to their default values ([Default values](#)). In all other cases, the initial content of a fixed size buffer is undefined.

Stack allocation

In an unsafe context, a local variable declaration ([Local variable declarations](#)) may include a stack allocation initializer which allocates memory from the call stack.

```
local_variable_initializer_unsafe
: stackalloc_initializer
;

stackalloc_initializer
: 'stackalloc' unmanaged_type '[' expression ']'
;
```

The *unmanaged_type* indicates the type of the items that will be stored in the newly allocated location, and the *expression* indicates the number of these items. Taken together, these specify the required allocation size. Since the size of a stack allocation cannot be negative, it is a compile-time error to specify the number of items as a *constant_expression* that evaluates to a negative value.

A stack allocation initializer of the form `stackalloc T[E]` requires `T` to be an unmanaged type ([Pointer types](#)) and `E` to be an expression of type `int`. The construct allocates `E * sizeof(T)` bytes from the call stack and returns a pointer, of type `T*`, to the newly allocated block. If `E` is a negative value, then the behavior is undefined. If `E` is zero, then no allocation is made, and the pointer returned is implementation-defined. If there is not enough memory available to allocate a block of the given size, a `System.StackOverflowException` is thrown.

The content of the newly allocated memory is undefined.

Stack allocation initializers are not permitted in `catch` or `finally` blocks ([The try statement](#)).

There is no way to explicitly free memory allocated using `stackalloc`. All stack allocated memory blocks created during the execution of a function member are automatically discarded when that function member returns. This corresponds to the `alloca` function, an extension commonly found in C and C++ implementations.

In the example

```

using System;

class Test
{
    static string IntToString(int value) {
        int n = value >= 0? value: -value;
        unsafe {
            char* buffer = stackalloc char[16];
            char* p = buffer + 16;
            do {
                *--p = (char)(n % 10 + '0');
                n /= 10;
            } while (n != 0);
            if (value < 0) *--p = '-';
            return new string(p, 0, (int)(buffer + 16 - p));
        }
    }

    static void Main() {
        Console.WriteLine(IntToString(12345));
        Console.WriteLine(IntToString(-999));
    }
}

```

a `stackalloc` initializer is used in the `IntToString` method to allocate a buffer of 16 characters on the stack. The buffer is automatically discarded when the method returns.

Dynamic memory allocation

Except for the `stackalloc` operator, C# provides no predefined constructs for managing non-garbage collected memory. Such services are typically provided by supporting class libraries or imported directly from the underlying operating system. For example, the `Memory` class below illustrates how the heap functions of an underlying operating system might be accessed from C#:

```

using System;
using System.Runtime.InteropServices;

public static unsafe class Memory
{
    // Handle for the process heap. This handle is used in all calls to the
    // HeapXXX APIs in the methods below.
    private static readonly IntPtr s_heap = GetProcessHeap();

    // Allocates a memory block of the given size. The allocated memory is
    // automatically initialized to zero.
    public static void* Alloc(int size)
    {
        void* result = HeapAlloc(s_heap, HEAP_ZERO_MEMORY, (UIntPtr)size);
        if (result == null) throw new OutOfMemoryException();
        return result;
    }

    // Copies count bytes from src to dst. The source and destination
    // blocks are permitted to overlap.
    public static void Copy(void* src, void* dst, int count)
    {
        byte* ps = (byte*)src;
        byte* pd = (byte*)dst;
        if (ps > pd)
        {
            for (; count != 0; count--) *pd++ = *ps++;
        }
        else if (ps < pd)
        {

```

```

        for (ps += count, pd += count; count != 0; count--) *--pd = *--ps;
    }
}

// Frees a memory block.
public static void Free(void* block)
{
    if (!HeapFree(s_heap, 0, block)) throw new InvalidOperationException();
}

// Re-allocates a memory block. If the reallocation request is for a
// larger size, the additional region of memory is automatically
// initialized to zero.
public static void* ReAlloc(void* block, int size)
{
    void* result = HeapReAlloc(s_heap, HEAP_ZERO_MEMORY, block, (UIntPtr)size);
    if (result == null) throw new OutOfMemoryException();
    return result;
}

// Returns the size of a memory block.
public static int SizeOf(void* block)
{
    int result = (int)HeapSize(s_heap, 0, block);
    if (result == -1) throw new InvalidOperationException();
    return result;
}

// Heap API flags
private const int HEAP_ZERO_MEMORY = 0x00000008;

// Heap API functions
[DllImport("kernel32")]
private static extern IntPtr GetProcessHeap();

[DllImport("kernel32")]
private static extern void* HeapAlloc(IntPtr hHeap, int flags, UIntPtr size);

[DllImport("kernel32")]
private static extern bool HeapFree(IntPtr hHeap, int flags, void* block);

[DllImport("kernel32")]
private static extern void* HeapReAlloc(IntPtr hHeap, int flags, void* block, UIntPtr size);

[DllImport("kernel32")]
private static extern UIntPtr HeapSize(IntPtr hHeap, int flags, void* block);
}

```

An example that uses the `Memory` class is given below:

```
class Test
{
    static unsafe void Main()
    {
        byte* buffer = null;
        try
        {
            const int Size = 256;
            buffer = (byte*)Memory.Alloc(Size);
            for (int i = 0; i < Size; i++) buffer[i] = (byte)i;
            byte[] array = new byte[Size];
            fixed (byte* p = array) Memory.Copy(buffer, p, Size);
            for (int i = 0; i < Size; i++) Console.WriteLine(array[i]);
        }
        finally
        {
            if (buffer != null) Memory.Free(buffer);
        }
    }
}
```

The example allocates 256 bytes of memory through `Memory.Alloc` and initializes the memory block with values increasing from 0 to 255. It then allocates a 256 element byte array and uses `Memory.Copy` to copy the contents of the memory block into the byte array. Finally, the memory block is freed using `Memory.Free` and the contents of the byte array are output on the console.

Documentation comments

12/28/2021 • 22 minutes to read • [Edit Online](#)

C# provides a mechanism for programmers to document their code using a special comment syntax that contains XML text. In source code files, comments having a certain form can be used to direct a tool to produce XML from those comments and the source code elements, which they precede. Comments using such syntax are called *documentation comments*. They must immediately precede a user-defined type (such as a class, delegate, or interface) or a member (such as a field, event, property, or method). The XML generation tool is called the *documentation generator*. (This generator could be, but need not be, the C# compiler itself.) The output produced by the documentation generator is called the *documentation file*. A documentation file is used as input to a *documentation viewer*, a tool intended to produce some sort of visual display of type information and its associated documentation.

This specification suggests a set of tags to be used in documentation comments, but use of these tags is not required, and other tags may be used if desired, as long the rules of well-formed XML are followed.

Introduction

Comments having a special form can be used to direct a tool to produce XML from those comments and the source code elements, which they precede. Such comments are single-line comments that start with three slashes (`///`), or delimited comments that start with a slash and two stars (`/**`). They must immediately precede a user-defined type (such as a class, delegate, or interface) or a member (such as a field, event, property, or method) that they annotate. Attribute sections ([Attribute specification](#)) are considered part of declarations, so documentation comments must precede attributes applied to a type or member.

Syntax:

```
single_line_doc_comment
    : '///' input_character*
    ;

delimited_doc_comment
    : '/**' delimited_comment_section* asterisk+ '/'
    ;
```

In a *single_line_doc_comment*, if there is a *whitespace* character following the `///` characters on each of the *single_line_doc_comments* adjacent to the current *single_line_doc_comment*, then that *whitespace* character is not included in the XML output.

In a delimited-doc-comment, if the first non-whitespace character on the second line is an asterisk and the same pattern of optional whitespace characters and an asterisk character is repeated at the beginning of each of the line within the delimited-doc-comment, then the characters of the repeated pattern are not included in the XML output. The pattern may include whitespace characters after, as well as before, the asterisk character.

Example:

```

/// <summary>Class <c>Point</c> models a point in a two-dimensional
/// plane.</summary>
///
public class Point
{
    /// <summary>method <c>draw</c> renders the point.</summary>
    void draw() {...}
}

```

The text within documentation comments must be well formed according to the rules of XML (<https://www.w3.org/TR/REC-xml>). If the XML is ill formed, a warning is generated and the documentation file will contain a comment saying that an error was encountered.

Although developers are free to create their own set of tags, a recommended set is defined in [Recommended tags](#). Some of the recommended tags have special meanings:

- The `<param>` tag is used to describe parameters. If such a tag is used, the documentation generator must verify that the specified parameter exists and that all parameters are described in documentation comments. If such verification fails, the documentation generator issues a warning.
- The `cref` attribute can be attached to any tag to provide a reference to a code element. The documentation generator must verify that this code element exists. If the verification fails, the documentation generator issues a warning. When looking for a name described in a `cref` attribute, the documentation generator must respect namespace visibility according to `using` statements appearing within the source code. For code elements that are generic, the normal generic syntax (that is, "`List<T>`") cannot be used because it produces invalid XML. Braces can be used instead of brackets (that is, "`List{T}`"), or the XML escape syntax can be used (that is, "`List<T>`").
- The `<summary>` tag is intended to be used by a documentation viewer to display additional information about a type or member.
- The `<include>` tag includes information from an external XML file.

Note carefully that the documentation file does not provide full information about the type and members (for example, it does not contain any type information). To get such information about a type or member, the documentation file must be used in conjunction with reflection on the actual type or member.

Recommended tags

The documentation generator must accept and process any tag that is valid according to the rules of XML. The following tags provide commonly used functionality in user documentation. (Of course, other tags are possible.)

TAG	SECTION	PURPOSE
<code><c></code>	<code><c></code>	Set text in a code-like font
<code><code></code>	<code><code></code>	Set one or more lines of source code or program output
<code><example></code>	<code><example></code>	Indicate an example
<code><exception></code>	<code><exception></code>	Identifies the exceptions a method can throw
<code><include></code>	<code><include></code>	Includes XML from an external file

TAG	SECTION	PURPOSE
<code><list></code>	<code><list></code>	Create a list or table
<code><para></code>	<code><para></code>	Permit structure to be added to text
<code><param></code>	<code><param></code>	Describe a parameter for a method or constructor
<code><paramref></code>	<code><paramref></code>	Identify that a word is a parameter name
<code><permission></code>	<code><permission></code>	Document the security accessibility of a member
<code><remarks></code>	<code><remarks></code>	Describe additional information about a type
<code><returns></code>	<code><returns></code>	Describe the return value of a method
<code><see></code>	<code><see></code>	Specify a link
<code><seealso></code>	<code><seealso></code>	Generate a See Also entry
<code><summary></code>	<code><summary></code>	Describe a type or a member of a type
<code><value></code>	<code><value></code>	Describe a property
<code><typeparam></code>		Describe a generic type parameter
<code><typeparamref></code>		Identify that a word is a type parameter name

`<c>`

This tag provides a mechanism to indicate that a fragment of text within a description should be set in a special font such as that used for a block of code. For lines of actual code, use `<code>` (`<code>`).

Syntax:

```
<c>text</c>
```

Example:

```
/// <summary>Class <c>Point</c> models a point in a two-dimensional
/// plane.</summary>

public class Point
{
    // ...
}
```

`<code>`

This tag is used to set one or more lines of source code or program output in some special font. For small code

fragments in narrative, use `<c>` (`<c>`).

Syntax:

```
<code>source code or program output</code>
```

Example:

```
/// <summary>This method changes the point's location by  
///     the given x- and y-offsets.  
/// <example>For example:  
/// <code>  
///     Point p = new Point(3,5);  
///     p.Translate(-1,3);  
/// </code>  
/// results in <c>p</c>'s having the value (2,8).  
/// </example>  
/// </summary>  
  
public void Translate(int xor, int yor) {  
    X += xor;  
    Y += yor;  
}
```

`<example>`

This tag allows example code within a comment, to specify how a method or other library member may be used. Ordinarily, this would also involve use of the tag `<code>` (`<code>`) as well.

Syntax:

```
<example>description</example>
```

Example:

See `<code>` (`<code>`) for an example.

`<exception>`

This tag provides a way to document the exceptions a method can throw.

Syntax:

```
<exception cref="member">description</exception>
```

where

- `member` is the name of a member. The documentation generator checks that the given member exists and translates `member` to the canonical element name in the documentation file.
- `description` is a description of the circumstances in which the exception is thrown.

Example:

```

public class DataBaseOperations
{
    /// <exception cref="MasterFileFormatException"></exception>
    /// <exception cref="MasterFileLockedOpenException"></exception>
    public static void ReadRecord(int flag) {
        if (flag == 1)
            throw new MasterFileFormatException();
        else if (flag == 2)
            throw new MasterFileLockedOpenException();
        // ...
    }
}

```

`<include>`

This tag allows including information from an XML document that is external to the source code file. The external file must be a well-formed XML document, and an XPath expression is applied to that document to specify what XML from that document to include. The `<include>` tag is then replaced with the selected XML from the external document.

Syntax:

```
<include file="filename" path="xpath" />
```

where

- `filename` is the file name of an external XML file. The file name is interpreted relative to the file that contains the include tag.
- `xpath` is an XPath expression that selects some of the XML in the external XML file.

Example:

If the source code contained a declaration like:

```

/// <include file="docs.xml" path='extradoc/class[@name="IntList"]/*' />
public class IntList { ... }

```

and the external file "docs.xml" had the following contents:

```

<?xml version="1.0"?>
<extradoc>
  <class name="IntList">
    <summary>
      Contains a list of integers.
    </summary>
  </class>
  <class name="StringList">
    <summary>
      Contains a list of integers.
    </summary>
  </class>
</extradoc>

```

then the same documentation is output as if the source code contained:

```

/// <summary>
///     Contains a list of integers.
/// </summary>
public class IntList { ... }

```

<list>

This tag is used to create a list or table of items. It may contain a <listheader> block to define the heading row of either a table or definition list. (When defining a table, only an entry for <term> in the heading need be supplied.)

Each item in the list is specified with an <item> block. When creating a definition list, both <term> and <description> must be specified. However, for a table, bulleted list, or numbered list, only <description> need be specified.

Syntax:

```

<list type="bullet" | "number" | "table">
  <listheader>
    <term>term</term>
    <description>*description*</description>
  </listheader>
  <item>
    <term>term</term>
    <description>*description*</description>
  </item>
  ...
  <item>
    <term>term</term>
    <description>description</description>
  </item>
</list>

```

where

- <term> is the term to define, whose definition is in <description> .
- <description> is either an item in a bullet or numbered list, or the definition of a <term> .

Example:

```

public class MyClass
{
    /// <summary>Here is an example of a bulleted list:
    /// <list type="bullet">
    /// <item>
    /// <description>Item 1.</description>
    /// </item>
    /// <item>
    /// <description>Item 2.</description>
    /// </item>
    /// </list>
    /// </summary>
    public static void Main () {
        // ...
    }
}

```

<para>

This tag is for use inside other tags, such as <summary> (<remarks>) or <returns> (<returns>), and permits

structure to be added to text.

Syntax:

```
<para>content</para>
```

where `content` is the text of the paragraph.

Example:

```
/// <summary>This is the entry point of the Point class testing program.
/// <para>This program tests each method and operator, and
/// is intended to be run after any non-trivial maintenance has
/// been performed on the Point class.</para></summary>
public static void Main() {
    // ...
}
```

```
<param>
```

This tag is used to describe a parameter for a method, constructor, or indexer.

Syntax:

```
<param name="name">description</param>
```

where

- `name` is the name of the parameter.
- `description` is a description of the parameter.

Example:

```
/// <summary>This method changes the point's location to
/// the given coordinates.</summary>
/// <param name="xor">the new x-coordinate.</param>
/// <param name="yor">the new y-coordinate.</param>
public void Move(int xor, int yor) {
    X = xor;
    Y = yor;
}
```

```
<paramref>
```

This tag is used to indicate that a word is a parameter. The documentation file can be processed to format this parameter in some distinct way.

Syntax:

```
<paramref name="name"/>
```

where `name` is the name of the parameter.

Example:

```

/// <summary>This constructor initializes the new Point to
///     (<paramref name="xor"/>,<paramref name="yor"/>).</summary>
/// <param name="xor">the new Point's x-coordinate.</param>
/// <param name="yor">the new Point's y-coordinate.</param>

public Point(int xor, int yor) {
    X = xor;
    Y = yor;
}

```

`<permission>`

This tag allows the security accessibility of a member to be documented.

Syntax:

```
<permission cref="member">description</permission>
```

where

- `member` is the name of a member. The documentation generator checks that the given code element exists and translates *member* to the canonical element name in the documentation file.
- `description` is a description of the access to the member.

Example:

```

/// <permission cref="System.Security.PermissionSet">Everyone can
/// access this method.</permission>

public static void Test() {
    // ...
}

```

`<remarks>`

This tag is used to specify extra information about a type. (Use `<summary>` (`<summary>`) to describe the type itself and the members of a type.)

Syntax:

```
<remarks>description</remarks>
```

where `description` is the text of the remark.

Example:

```

/// <summary>Class <c>Point</c> models a point in a
/// two-dimensional plane.</summary>
/// <remarks>Uses polar coordinates</remarks>
public class Point
{
    // ...
}

```

`<returns>`

This tag is used to describe the return value of a method.

Syntax:

```
<returns>description</returns>
```

where `description` is a description of the return value.

Example:

```
/// <summary>Report a point's location as a string.</summary>
/// <returns>A string representing a point's location, in the form (x,y),
///     without any leading, trailing, or embedded whitespace.</returns>
public override string ToString() {
    return "(" + X + ", " + Y + ")";
}
```

```
<see>
```

This tag allows a link to be specified within text. Use `<seealso>` (`<seealso>`) to indicate text that is to appear in a See Also section.

Syntax:

```
<see cref="member"/>
```

where `member` is the name of a member. The documentation generator checks that the given code element exists and changes *member* to the element name in the generated documentation file.

Example:

```
/// <summary>This method changes the point's location to
///     the given coordinates.</summary>
/// <see cref="Translate"/>
public void Move(int xor, int yor) {
    X = xor;
    Y = yor;
}

/// <summary>This method changes the point's location by
///     the given x- and y-offsets.
/// </summary>
/// <see cref="Move"/>
public void Translate(int xor, int yor) {
    X += xor;
    Y += yor;
}
```

```
<seealso>
```

This tag allows an entry to be generated for the See Also section. Use `<see>` (`<see>`) to specify a link from within text.

Syntax:

```
<seealso cref="member"/>
```

where `member` is the name of a member. The documentation generator checks that the given code element exists and changes *member* to the element name in the generated documentation file.

Example:

```
/// <summary>This method determines whether two Points have the same
///     location.</summary>
/// <seealso cref="operator==">
/// <seealso cref="operator!=">
public override bool Equals(object o) {
    // ...
}
```

`<summary>`

This tag can be used to describe a type or a member of a type. Use `<remarks>` (`<remarks>`) to describe the type itself.

Syntax:

```
<summary>description</summary>
```

where `description` is a summary of the type or member.

Example:

```
/// <summary>This constructor initializes the new Point to (0,0).</summary>
public Point() : this(0,0) {
}
```

`<value>`

This tag allows a property to be described.

Syntax:

```
<value>property description</value>
```

where `property description` is a description for the property.

Example:

```
/// <value>Property <c>X</c> represents the point's x-coordinate.</value>
public int X
{
    get { return x; }
    set { x = value; }
}
```

`<typeparam>`

This tag is used to describe a generic type parameter for a class, struct, interface, delegate, or method.

Syntax:

```
<typeparam name="name">description</typeparam>
```

where `name` is the name of the type parameter, and `description` is its description.

Example:

```
/// <summary>A generic list class.</summary>
/// <typeparam name="T">The type stored by the list.</typeparam>
public class MyList<T> {
    ...
}
```

`<typeparamref>`

This tag is used to indicate that a word is a type parameter. The documentation file can be processed to format this type parameter in some distinct way.

Syntax:

```
<typeparamref name="name"/>
```

where `name` is the name of the type parameter.

Example:

```
/// <summary>This method fetches data and returns a list of <typeparamref name="T"/>.</summary>
/// <param name="query">query to execute</param>
public List<T> FetchData<T>(string query) {
    ...
}
```

Processing the documentation file

The documentation generator generates an ID string for each element in the source code that is tagged with a documentation comment. This ID string uniquely identifies a source element. A documentation viewer can use an ID string to identify the corresponding metadata/reflection item to which the documentation applies.

The documentation file is not a hierarchical representation of the source code; rather, it is a flat list with a generated ID string for each element.

ID string format

The documentation generator observes the following rules when it generates the ID strings:

- No white space is placed in the string.
- The first part of the string identifies the kind of member being documented, via a single character followed by a colon. The following kinds of members are defined:

CHARACTER	DESCRIPTION
E	Event
F	Field
M	Method (including constructors, destructors, and operators)
N	Namespace
P	Property (including indexers)

CHARACTER	DESCRIPTION
T	Type (such as class, delegate, enum, interface, and struct)
!	Error string; the rest of the string provides information about the error. For example, the documentation generator generates error information for links that cannot be resolved.

- The second part of the string is the fully qualified name of the element, starting at the root of the namespace. The name of the element, its enclosing type(s), and namespace are separated by periods. If the name of the item itself has periods, they are replaced by `#(U+0023)` characters. (It is assumed that no element has this character in its name.)
- For methods and properties with arguments, the argument list follows, enclosed in parentheses. For those without arguments, the parentheses are omitted. The arguments are separated by commas. The encoding of each argument is the same as a CLI signature, as follows:
 - Arguments are represented by their documentation name, which is based on their fully qualified name, modified as follows:
 - Arguments that represent generic types have an appended ``` (backtick) character followed by the number of type parameters
 - Arguments having the `out` or `ref` modifier have an `@` following their type name. Arguments passed by value or via `params` have no special notation.
 - Arguments that are arrays are represented as `[lowerbound:size, ... , lowerbound:size]` where the number of commas is the rank less one, and the lower bounds and size of each dimension, if known, are represented in decimal. If a lower bound or size is not specified, it is omitted. If the lower bound and size for a particular dimension are omitted, the `:` is omitted as well. Jagged arrays are represented by one `[]` per level.
 - Arguments that have pointer types other than void are represented using a `*` following the type name. A void pointer is represented using a type name of `System.Void`.
 - Arguments that refer to generic type parameters defined on types are encoded using the ``` (backtick) character followed by the zero-based index of the type parameter.
 - Arguments that use generic type parameters defined in methods use a double-backtick ```` instead of the ``` used for types.
 - Arguments that refer to constructed generic types are encoded using the generic type, followed by `{`, followed by a comma-separated list of type arguments, followed by `}`.

ID string examples

The following examples each show a fragment of C# code, along with the ID string produced from each source element capable of having a documentation comment:

- Types are represented using their fully qualified name, augmented with generic information:

```

enum Color { Red, Blue, Green }

namespace Acme
{
    interface IProcess {...}

    struct ValueType {...}

    class Widget: IProcess
    {
        public class NestedClass {...}
        public interface IMenuItem {...}
        public delegate void Del(int i);
        public enum Direction { North, South, East, West }
    }

    class MyList<T>
    {
        class Helper<U,V> {...}
    }
}

"T:Color"
"T:Acme.IProcess"
"T:Acme.ValueType"
"T:Acme.Widget"
"T:Acme.Widget.NestedClass"
"T:Acme.Widget.IMenuItem"
"T:Acme.Widget.Del"
"T:Acme.Widget.Direction"
"T:Acme.MyList`1"
"T:Acme.MyList`1.Helper`2"

```

- Fields are represented by their fully qualified name:

```

namespace Acme
{
    struct ValueType
    {
        private int total;
    }

    class Widget: IProcess
    {
        public class NestedClass
        {
            private int value;
        }

        private string message;
        private static Color defaultColor;
        private const double PI = 3.14159;
        protected readonly double monthlyAverage;
        private long[] array1;
        private Widget[,] array2;
        private unsafe int *pCount;
        private unsafe float **ppValues;
    }
}

"F:Acme.ValueType.total"
"F:Acme.Widget.NestedClass.value"
"F:Acme.Widget.message"
"F:Acme.Widget.defaultColor"
"F:Acme.Widget.PI"
"F:Acme.Widget.monthlyAverage"
"F:Acme.Widget.array1"
"F:Acme.Widget.array2"
"F:Acme.Widget.pCount"
"F:Acme.Widget.ppValues"

```

- Constructors.

```

namespace Acme
{
    class Widget: IProcess
    {
        static Widget() {...}
        public Widget() {...}
        public Widget(string s) {...}
    }
}

"M:Acme.Widget.#cctor"
"M:Acme.Widget.#ctor"
"M:Acme.Widget.#ctor(System.String)"

```

- Destructors.

```

namespace Acme
{
    class Widget: IProcess
    {
        ~Widget() {...}
    }
}

"M:Acme.Widget.Finalize"

```

- Methods.

```
namespace Acme
{
    struct ValueType
    {
        public void M(int i) {...}
    }

    class Widget: IProcess
    {
        public class NestedClass
        {
            public void M(int i) {...}
        }

```

An example

C# source code

The following example shows the source code of a `Point` class:

```

namespace Graphics
{
    /// <summary>Class <c>Point</c> models a point in a two-dimensional plane.
    /// </summary>
    public class Point
    {
        /// <summary>Instance variable <c>x</c> represents the point's
        ///     x-coordinate.</summary>
        private int x;

        /// <summary>Instance variable <c>y</c> represents the point's
        ///     y-coordinate.</summary>
        private int y;

        /// <value>Property <c>X</c> represents the point's x-coordinate.</value>
        public int X
        {
            get { return x; }
            set { x = value; }
        }

        /// <value>Property <c>Y</c> represents the point's y-coordinate.</value>
        public int Y
        {
            get { return y; }
            set { y = value; }
        }

        /// <summary>This constructor initializes the new Point to
        ///     (0,0).</summary>
        public Point() : this(0,0) {}

        /// <summary>This constructor initializes the new Point to
        ///     (<paramref name="xor"/>,<paramref name="yor"/>).</summary>
        /// <param><c>xor</c> is the new Point's x-coordinate.</param>
        /// <param><c>yor</c> is the new Point's y-coordinate.</param>
        public Point(int xor, int yor) {
            X = xor;
            Y = yor;
        }

        /// <summary>This method changes the point's location to
        ///     the given coordinates.</summary>
        /// <param><c>xor</c> is the new x-coordinate.</param>
        /// <param><c>yor</c> is the new y-coordinate.</param>
    }
}

```

```

/// <see cref="Translate"/>

Pattern Matching for C# 7

12/28/2021 • 15 minutes to read • [Edit Online](#)

Pattern matching extensions for C# enable many of the benefits of algebraic data types and pattern matching from functional languages, but in a way that smoothly integrates with the feel of the underlying language. The basic features are: [record types](#), which are types whose semantic meaning is described by the shape of the data; and pattern matching, which is a new expression form that enables extremely concise multilevel decomposition of these data types. Elements of this approach are inspired by related features in the programming languages [F#](#) and [Scala](#).

Is expression

The `is` operator is extended to test an expression against a *pattern*.

```
relational_expression
    : relational_expression 'is' pattern
    ;
```

This form of *relational_expression* is in addition to the existing forms in the C# specification. It is a compile-time error if the *relational_expression* to the left of the `is` token does not designate a value or does not have a type.

Every *identifier* of the pattern introduces a new local variable that is *definitely assigned* after the `is` operator is `true` (i.e. *definitely assigned when true*).

Note: There is technically an ambiguity between *type* in an `is-expression` and *constant_pattern*, either of which might be a valid parse of a qualified identifier. We try to bind it as a type for compatibility with previous versions of the language; only if that fails do we resolve it as we do in other contexts, to the first thing found (which must be either a constant or a type). This ambiguity is only present on the right-hand-side of an `is` expression.

Patterns

Patterns are used in the `is` operator and in a *switch_statement* to express the shape of data against which incoming data is to be compared. Patterns may be recursive so that parts of the data may be matched against sub-patterns.

```

pattern
    : declaration_pattern
    | constant_pattern
    | var_pattern
    ;

declaration_pattern
    : type simple_designation
    ;

constant_pattern
    : shift_expression
    ;

var_pattern
    : 'var' simple_designation
    ;

```

Note: There is technically an ambiguity between *type* in an `is-expression` and *constant_pattern*, either of which might be a valid parse of a qualified identifier. We try to bind it as a type for compatibility with previous versions of the language; only if that fails do we resolve it as we do in other contexts, to the first thing found (which must be either a constant or a type). This ambiguity is only present on the right-hand-side of an `is` expression.

Declaration pattern

The *declaration_pattern* both tests that an expression is of a given type and casts it to that type if the test succeeds. If the *simple_designation* is an identifier, it introduces a local variable of the given type named by the given identifier. That local variable is *definitely assigned* when the result of the pattern-matching operation is true.

```

declaration_pattern
    : type simple_designation
    ;

```

The runtime semantic of this expression is that it tests the runtime type of the left-hand *relational_expression* operand against the *type* in the pattern. If it is of that runtime type (or some subtype), the result of the `is operator` is `true`. It declares a new local variable named by the *identifier* that is assigned the value of the left-hand operand when the result is `true`.

Certain combinations of static type of the left-hand-side and the given type are considered incompatible and result in compile-time error. A value of static type `E` is said to be *pattern compatible* with the type `T` if there exists an identity conversion, an implicit reference conversion, a boxing conversion, an explicit reference conversion, or an unboxing conversion from `E` to `T`. It is a compile-time error if an expression of type `E` is not pattern compatible with the type in a type pattern that it is matched with.

Note: In C# 7.1 we extend this to permit a pattern-matching operation if either the input type or the type `T` is an open type. This paragraph is replaced by the following:

Certain combinations of static type of the left-hand-side and the given type are considered incompatible and result in compile-time error. A value of static type `E` is said to be *pattern compatible* with the type `T` if there exists an identity conversion, an implicit reference conversion, a boxing conversion, an explicit reference conversion, or an unboxing conversion from `E` to `T`, or if either `E` or `T` is an open type. It is a compile-time error if an expression of type `E` is not pattern compatible with the type in a type pattern that it is matched with.

The declaration pattern is useful for performing run-time type tests of reference types, and replaces the idiom

```
var v = expr as Type;
if (v != null) { // code using v }
```

With the slightly more concise

```
if (expr is Type v) { // code using v }
```

It is an error if *type* is a nullable value type.

The declaration pattern can be used to test values of nullable types: a value of type `Nullable<T>` (or a boxed `T`) matches a type pattern `T2 id` if the value is non-null and the type of `T2` is `T`, or some base type or interface of `T`. For example, in the code fragment

```
int? x = 3;
if (x is int v) { // code using v }
```

The condition of the `if` statement is `true` at runtime and the variable `v` holds the value `3` of type `int` inside the block.

Constant pattern

```
constant_pattern
: shift_expression
;
```

A constant pattern tests the value of an expression against a constant value. The constant may be any constant expression, such as a literal, the name of a declared `const` variable, or an enumeration constant, or a `typeof` expression.

If both *e* and *c* are of integral types, the pattern is considered matched if the result of the expression `e == c` is `true`.

Otherwise the pattern is considered matching if `object.Equals(e, c)` returns `true`. In this case it is a compile-time error if the static type of *e* is not *pattern compatible* with the type of the constant.

Var pattern

```
var_pattern
: 'var' simple_designation
;
```

An expression *e* matches a *var_pattern* always. In other words, a match to a *var pattern* always succeeds. If the *simple_designation* is an identifier, then at runtime the value of *e* is bound to a newly introduced local variable. The type of the local variable is the static type of *e*.

It is an error if the name `var` binds to a type.

Switch statement

The `switch` statement is extended to select for execution the first block having an associated pattern that matches the *switch expression*.

```

switch_label
  : 'case' complex_pattern case_guard? ':'
  | 'case' constant_expression case_guard? ':'
  | 'default' ':'
  ;

case_guard
  : 'when' expression
  ;

```

The order in which patterns are matched is not defined. A compiler is permitted to match patterns out of order, and to reuse the results of already matched patterns to compute the result of matching of other patterns.

If a *case-guard* is present, its expression is of type `bool`. It is evaluated as an additional condition that must be satisfied for the case to be considered satisfied.

It is an error if a *switch_label* can have no effect at runtime because its pattern is subsumed by previous cases. [TODO: We should be more precise about the techniques the compiler is required to use to reach this judgment.]

A pattern variable declared in a *switch_label* is definitely assigned in its case block if and only if that case block contains precisely one *switch_label*.

[TODO: We should specify when a *switch block* is reachable.]

Scope of pattern variables

The scope of a variable declared in a pattern is as follows:

- If the pattern is a case label, then the scope of the variable is the *case block*.

Otherwise the variable is declared in an *is_pattern* expression, and its scope is based on the construct immediately enclosing the expression containing the *is_pattern* expression as follows:

- If the expression is in an expression-bodied lambda, its scope is the body of the lambda.
- If the expression is in an expression-bodied method or property, its scope is the body of the method or property.
- If the expression is in a `when` clause of a `catch` clause, its scope is that `catch` clause.
- If the expression is in an *iteration_statement*, its scope is just that statement.
- Otherwise if the expression is in some other statement form, its scope is the scope containing the statement.

For the purpose of determining the scope, an *embedded_statement* is considered to be in its own scope. For example, the grammar for an *if_statement* is

```

if_statement
  : 'if' '(' boolean_expression ')' embedded_statement
  | 'if' '(' boolean_expression ')' embedded_statement 'else' embedded_statement
  ;

```

So if the controlled statement of an *if_statement* declares a pattern variable, its scope is restricted to that *embedded_statement*.

```
if (x) M(y is var z);
```

In this case the scope of `z` is the embedded statement `M(y is var z);`.

Other cases are errors for other reasons (e.g. in a parameter's default value or an attribute, both of which are an error because those contexts require a constant expression).

In C# 7.3 we added the following contexts in which a pattern variable may be declared:

- If the expression is in a *constructor initializer*, its scope is the *constructor initializer* and the constructor's body.
- If the expression is in a field initializer, its scope is the *equals_value_clause* in which it appears.
- If the expression is in a query clause that is specified to be translated into the body of a lambda, its scope is just that expression.

Changes to syntactic disambiguation

There are situations involving generics where the C# grammar is ambiguous, and the language spec says how to resolve those ambiguities:

7.6.5.2 Grammar ambiguities

The productions for *simple-name* (§7.6.3) and *member-access* (§7.6.5) can give rise to ambiguities in the grammar for expressions. For example, the statement:

```
F(G<A,B>(7));
```

could be interpreted as a call to `F` with two arguments, `G < A` and `B > (7)`. Alternatively, it could be interpreted as a call to `F` with one argument, which is a call to a generic method `G` with two type arguments and one regular argument.

If a sequence of tokens can be parsed (in context) as a *simple-name* (§7.6.3), *member-access* (§7.6.5), or *pointer-member-access* (§18.5.2) ending with a *type-argument-list* (§4.4.1), the token immediately following the closing `>` token is examined. If it is one of

```
( ) ] } : ; , . ? == != | ^
```

then the *type-argument-list* is retained as part of the *simple-name*, *member-access* or *pointer-member-access* and any other possible parse of the sequence of tokens is discarded. Otherwise, the *type-argument-list* is not considered to be part of the *simple-name*, *member-access* or *> pointer-member-access*, even if there is no other possible parse of the sequence of tokens. Note that these rules are not applied when parsing a *type-argument-list* in a *namespace-or-type-name* (§3.8). The statement

```
F(G<A,B>(7));
```

will, according to this rule, be interpreted as a call to `F` with one argument, which is a call to a generic method `G` with two type arguments and one regular argument. The statements

```
F(G < A, B > 7);  
F(G < A, B >> 7);
```

will each be interpreted as a call to `F` with two arguments. The statement

```
x = F < A > +y;
```

will be interpreted as a less than operator, greater than operator, and unary plus operator, as if the statement had been written `x = (F < A) > (+y)`, instead of as a *simple-name* with a *type-argument-list* followed by a binary plus operator. In the statement

```
x = y is C<T> + z;
```

the tokens `C<T>` are interpreted as a *namespace-or-type-name* with a *type-argument-list*.

There are a number of changes being introduced in C# 7 that make these disambiguation rules no longer sufficient to handle the complexity of the language.

Out variable declarations

It is now possible to declare a variable in an out argument:

```
M(out Type name);
```

However, the type may be generic:

```
M(out A<B> name);
```

Since the language grammar for the argument uses *expression*, this context is subject to the disambiguation rule. In this case the closing `>` is followed by an *identifier*, which is not one of the tokens that permits it to be treated as a *type-argument-list*. I therefore propose to **add *identifier* to the set of tokens that triggers the disambiguation to a *type-argument-list*.**

Tuples and deconstruction declarations

A tuple literal runs into exactly the same issue. Consider the tuple expression

```
(A < B, C > D, E < F, G > H)
```

Under the old C# 6 rules for parsing an argument list, this would parse as a tuple with four elements, starting with `A < B` as the first. However, when this appears on the left of a deconstruction, we want the disambiguation triggered by the *identifier* token as described above:

```
(A<B,C> D, E<F,G> H) = e;
```

This is a deconstruction declaration which declares two variables, the first of which is of type `A<B,C>` and named `D`. In other words, the tuple literal contains two expressions, each of which is a declaration expression.

For simplicity of the specification and compiler, I propose that this tuple literal be parsed as a two-element tuple wherever it appears (whether or not it appears on the left-hand-side of an assignment). That would be a natural result of the disambiguation described in the previous section.

Pattern-matching

Pattern matching introduces a new context where the expression-type ambiguity arises. Previously the right-hand-side of an `is` operator was a type. Now it can be a type or expression, and if it is a type it may be followed by an identifier. This can, technically, change the meaning of existing code:

```
var x = e is T < A > B;
```

This could be parsed under C#6 rules as

```
var x = ((e is T) < A) > B;
```

but under C#7 rules (with the disambiguation proposed above) would be parsed as

```
var x = e is T<A> B;
```

which declares a variable `B` of type `T<A>`. Fortunately, the native and Roslyn compilers have a bug whereby they give a syntax error on the C#6 code. Therefore this particular breaking change is not a concern.

Pattern-matching introduces additional tokens that should drive the ambiguity resolution toward selecting a type. The following examples of existing valid C#6 code would be broken without additional disambiguation rules:

```
var x = e is A<B> && f;           // &&
var x = e is A<B> || f;           // ||
var x = e is A<B> & f;            // &
var x = e is A<B>[];              // [
```

Proposed change to the disambiguation rule

I propose to revise the specification to change the list of disambiguating tokens from

```
( ) ] } : ; , . ? == != | ^
```

to

```
( ) ] } : ; , . ? == != | ^ && || & [
```

And, in certain contexts, we treat *identifier* as a disambiguating token. Those contexts are where the sequence of tokens being disambiguated is immediately preceded by one of the keywords `is`, `case`, or `out`, or arises while parsing the first element of a tuple literal (in which case the tokens are preceded by `(` or `:` and the identifier is followed by a `,`) or a subsequent element of a tuple literal.

Modified disambiguation rule

The revised disambiguation rule would be something like this

If a sequence of tokens can be parsed (in context) as a *simple-name* (§7.6.3), *member-access* (§7.6.5), or *pointer-member-access* (§18.5.2) ending with a *type-argument-list* (§4.4.1), the token immediately following the closing `>` token is examined, to see if it is

- One of `()] } : ; , . ? == != | ^ && || & [`; or
- One of the relational operators `< > <= >= is as`; or
- A contextual query keyword appearing inside a query expression; or
- In certain contexts, we treat *identifier* as a disambiguating token. Those contexts are where the sequence of tokens being disambiguated is immediately preceded by one of the keywords `is`, `case` or `out`, or arises while parsing the first element of a tuple literal (in which case the tokens are preceded by `(` or `:` and the identifier is followed by a `,`) or a subsequent element of a tuple literal.

If the following token is among this list, or an identifier in such a context, then the *type-argument-list* is retained as part of the *simple-name*, *member-access* or *pointer-member-access* and any other possible parse of the sequence of tokens is discarded. Otherwise, the *type-argument-list* is not considered to be part of the *simple-name*, *member-access* or *pointer-member-access*, even if there is no other possible parse of the sequence of tokens. Note that these rules are not applied when parsing a *type-argument-list* in a

namespace-or-type-name (§3.8).

Breaking changes due to this proposal

No breaking changes are known due to this proposed disambiguation rule.

Interesting examples

Here are some interesting results of these disambiguation rules:

The expression `(A < B, C > D)` is a tuple with two elements, each a comparison.

The expression `(A<B,C> D, E)` is a tuple with two elements, the first of which is a declaration expression.

The invocation `M(A < B, C > D, E)` has three arguments.

The invocation `M(out A<B,C> D, E)` has two arguments, the first of which is an `out` declaration.

The expression `e is A C` uses a declaration expression.

The case label `case A C:` uses a declaration expression.

Some examples of pattern matching

Is-As

We can replace the idiom

```
var v = expr as Type;
if (v != null) {
    // code using v
}
```

With the slightly more concise and direct

```
if (expr is Type v) {
    // code using v
}
```

Testing nullable

We can replace the idiom

```
Type? v = x?.y?.z;
if (v.HasValue) {
    var value = v.GetValueOrDefault();
    // code using value
}
```

With the slightly more concise and direct

```
if (x?.y?.z is Type value) {
    // code using value
}
```

Arithmetic simplification

Suppose we define a set of recursive types to represent expressions (per a separate proposal):

```
abstract class Expr;
class X() : Expr;
class Const(double Value) : Expr;
class Add(Expr Left, Expr Right) : Expr;
class Mult(Expr Left, Expr Right) : Expr;
class Neg(Expr Value) : Expr;
```

Now we can define a function to compute the (unreduced) derivative of an expression:

```
Expr Deriv(Expr e)
{
    switch (e) {
        case X(): return Const(1);
        case Const(*): return Const(0);
        case Add(var Left, var Right):
            return Add(Deriv(Left), Deriv(Right));
        case Mult(var Left, var Right):
            return Add(Mult(Deriv(Left), Right), Mult(Left, Deriv(Right)));
        case Neg(var Value):
            return Neg(Deriv(Value));
    }
}
```

An expression simplifier demonstrates positional patterns:

```
Expr Simplify(Expr e)
{
    switch (e) {
        case Mult(Const(0), *): return Const(0);
        case Mult(*, Const(0)): return Const(0);
        case Mult(Const(1), var x): return Simplify(x);
        case Mult(var x, Const(1)): return Simplify(x);
        case Mult(Const(var l), Const(var r)): return Const(l*r);
        case Add(Const(0), var x): return Simplify(x);
        case Add(var x, Const(0)): return Simplify(x);
        case Add(Const(var l), Const(var r)): return Const(l+r);
        case Neg(Const(var k)): return Const(-k);
        default: return e;
    }
}
```

Local functions

12/28/2021 • 2 minutes to read • [Edit Online](#)

We extend C# to support the declaration of functions in block scope. Local functions may use (capture) variables from the enclosing scope.

The compiler uses flow analysis to detect which variables a local function uses before assigning it a value. Every call of the function requires such variables to be definitely assigned. Similarly the compiler determines which variables are definitely assigned on return. Such variables are considered definitely assigned after the local function is invoked.

Local functions may be called from a lexical point before its definition. Local function declaration statements do not cause a warning when they are not reachable.

TODO: *WRITE SPEC*

Syntax grammar

This grammar is represented as a diff from the current spec grammar.

```
declaration-statement
    : local-variable-declaration ';'
    | local-constant-declaration ';'
+   | local-function-declaration
    ;

+local-function-declaration
+   : local-function-header local-function-body
+   ;

+local-function-header
+   : local-function-modifiers? return-type identifier type-parameter-list?
+     ( formal-parameter-list? ) type-parameter-constraints-clauses
+   ;

+local-function-modifiers
+   : (async | unsafe)
+   ;

+local-function-body
+   : block
+   | arrow-expression-body
+   ;
```

Local functions may use variables defined in the enclosing scope. The current implementation requires that every variable read inside a local function be definitely assigned, as if executing the local function at its point of definition. Also, the local function definition must have been "executed" at any use point.

After experimenting with that a bit (for example, it is not possible to define two mutually recursive local functions), we've since revised how we want the definite assignment to work. The revision (not yet implemented) is that all local variables read in a local function must be definitely assigned at each invocation of the local function. That's actually more subtle than it sounds, and there is a bunch of work remaining to make it work. Once it is done you'll be able to move your local functions to the end of its enclosing block.

The new definite assignment rules are incompatible with inferring the return type of a local function, so we'll likely be removing support for inferring the return type.

Unless you convert a local function to a delegate, capturing is done into frames that are value types. That means you don't get any GC pressure from using local functions with capturing.

Reachability

We add to the spec

The body of a statement-bodied lambda expression or local function is considered reachable.

Out variable declarations

12/28/2021 • 2 minutes to read • [Edit Online](#)

The *out variable declaration* feature enables a variable to be declared at the location that it is being passed as an `out` argument.

```
argument_value
: 'out' type identifier
| ...
;
```

A variable declared this way is called an *out variable*. You may use the contextual keyword `var` for the variable's type. The scope will be the same as for a *pattern-variable* introduced via pattern-matching.

According to Language Specification (section 7.6.7 Element access) the argument-list of an element-access (indexing expression) does not contain `ref` or `out` arguments. However, they are permitted by the compiler for various scenarios, for example indexers declared in metadata that accept `out`.

Within the scope of a local variable introduced by an `argument_value`, it is a compile-time error to refer to that local variable in a textual position that precedes its declaration.

It is also an error to reference an implicitly-typed (§8.5.1) `out` variable in the same argument list that immediately contains its declaration.

Overload resolution is modified as follows:

We add a new conversion:

There is a *conversion from expression* from an implicitly-typed `out` variable declaration to every type.

Also

The type of an explicitly-typed `out` variable argument is the declared type.

and

An implicitly-typed `out` variable argument has no type.

The *conversion from expression* from an implicitly-typed `out` variable declaration is not considered better than any other *conversion from expression*.

The type of an implicitly-typed `out` variable is the type of the corresponding parameter in the signature of the method selected by overload resolution.

The new syntax node `DeclarationExpressionSyntax` is added to represent the declaration in an `out var` argument.

Throw expression

12/28/2021 • 2 minutes to read • [Edit Online](#)

We extend the set of expression forms to include

```
throw_expression
: 'throw' null_coalescing_expression
;

null_coalescing_expression
: throw_expression
;
```

The type rules are as follows:

- A *throw_expression* has no type.
- A *throw_expression* is convertible to every type by an implicit conversion.

A *throw expression* throws the value produced by evaluating the *null_coalescing_expression*, which must denote a value of the class type `System.Exception`, of a class type that derives from `System.Exception` or of a type parameter type that has `System.Exception` (or a subclass thereof) as its effective base class. If evaluation of the expression produces `null`, a `System.NullReferenceException` is thrown instead.

The behavior at runtime of the evaluation of a *throw expression* is the same [as specified for a *throw statement*](#).

The flow-analysis rules are as follows:

- For every variable v , v is definitely assigned before the *null_coalescing_expression* of a *throw_expression* iff it is definitely assigned before the *throw_expression*.
- For every variable v , v is definitely assigned after *throw_expression*.

A *throw expression* is permitted in only the following syntactic contexts:

- As the second or third operand of a ternary conditional operator `?:`
- As the second operand of a null coalescing operator `??`
- As the body of an expression-bodied lambda or method.

Binary literals

12/28/2021 • 2 minutes to read • [Edit Online](#)

There's a relatively common request to add binary literals to C# and VB. For bitmasks (e.g. flag enums) this seems genuinely useful, but it would also be great just for educational purposes.

Binary literals would look like this:

```
int nineteen = 0b10011;
```

Syntactically and semantically they are identical to hexadecimal literals, except for using `b` / `B` instead of `x` / `X`, having only digits `0` and `1` and being interpreted in base 2 instead of 16.

There's little cost to implementing these, and little conceptual overhead to users of the language.

Syntax

The grammar would be as follows:

```
integer-literal:
    : ...
    | binary-integer-literal
    ;
binary-integer-literal:
    : `0b` binary-digits integer-type-suffix-opt
    | `0B` binary-digits integer-type-suffix-opt
    ;
binary-digits:
    : binary-digit
    | binary-digits binary-digit
    ;
binary-digit:
    : `0`
    | `1`
    ;
```

Digit separators

12/28/2021 • 2 minutes to read • [Edit Online](#)

Being able to group digits in large numeric literals would have great readability impact and no significant downside.

Adding binary literals (#215) would increase the likelihood of numeric literals being long, so the two features enhance each other.

We would follow Java and others, and use an underscore `_` as a digit separator. It would be able to occur everywhere in a numeric literal (except as the first and last character), since different groupings may make sense in different scenarios and especially for different numeric bases:

```
int bin = 0b1001_1010_0001_0100;  
int hex = 0x1b_a0_44_fe;  
int dec = 33_554_432;  
int weird = 1_2_3_4_5_6_7_8_9;  
double real = 1_000.111_1e-1_000;
```

Any sequence of digits may be separated by underscores, possibly more than one underscore between two consecutive digits. They are allowed in decimals as well as exponents, but following the previous rule, they may not appear next to the decimal (`10_.0`), next to the exponent character (`1.1e_1`), or next to the type specifier (`10_f`). When used in binary and hexadecimal literals, they may not appear immediately following the `0x` or `0b`.

The syntax is straightforward, and the separators have no semantic impact - they are simply ignored.

This has broad value and is easy to implement.

Async Task Types in C#

12/28/2021 • 3 minutes to read • [Edit Online](#)

Extend `async` to support *task types* that match a specific pattern, in addition to the well known types

`System.Threading.Tasks.Task` and `System.Threading.Tasks.Task<T>`.

Task Type

A *task type* is a `class` or `struct` with an associated *builder type* identified with `System.Runtime.CompilerServices.AsyncMethodBuilderAttribute`. The *task type* may be non-generic, for async methods that do not return a value, or generic, for methods that return a value.

To support `await`, the *task type* must have a corresponding, accessible `GetAwaiter()` method that returns an instance of an *awaiter type* (see *C# 7.7.7.1 Awaitable expressions*).

```
[AsyncMethodBuilder(typeof(MyTaskMethodBuilder<>))]  
class MyTask<T>  
{  
    public Awaiter<T> GetAwaiter();  
}  
  
class Awaiter<T> : INotifyCompletion  
{  
    public bool IsCompleted { get; }  
    public T GetResult();  
    public void OnCompleted(Action completion);  
}
```

Builder Type

The *builder type* is a `class` or `struct` that corresponds to the specific *task type*. The *builder type* can have at most 1 type parameter and must not be nested in a generic type. The *builder type* has the following `public` methods. For non-generic *builder types*, `SetResult()` has no parameters.

```

class MyTaskMethodBuilder<T>
{
    public static MyTaskMethodBuilder<T> Create();

    public void Start<TStateMachine>(ref TStateMachine stateMachine)
        where TStateMachine : IAsyncStateMachine;

    public void SetStateMachine(IAsyncStateMachine stateMachine);
    public void SetException(Exception exception);
    public void SetResult(T result);

    public void AwaitOnCompleted<TAwaiter, TStateMachine>(
        ref TAwaiter awaiter, ref TStateMachine stateMachine)
        where TAwaiter : INotifyCompletion
        where TStateMachine : IAsyncStateMachine;
    public void AwaitUnsafeOnCompleted<TAwaiter, TStateMachine>(
        ref TAwaiter awaiter, ref TStateMachine stateMachine)
        where TAwaiter : ICriticalNotifyCompletion
        where TStateMachine : IAsyncStateMachine;

    public MyTask<T> Task { get; }
}

```

Execution

The types above are used by the compiler to generate the code for the state machine of an `async` method. (The generated code is equivalent to the code generated for `async` methods that return `Task`, `Task<T>`, or `void`. The difference is, for those well known types, the *builder types* are also known to the compiler.)

`Builder.Create()` is invoked to create an instance of the *builder type*.

`builder.Start(ref stateMachine)` is invoked to associate the builder with compiler-generated state machine instance. The builder must call `stateMachine.MoveNext()` either in `Start()` or after `Start()` has returned to advance the state machine. After `Start()` returns, the `async` method calls `builder.Task` for the task to return from the `async` method.

Each call to `stateMachine.MoveNext()` will advance the state machine. If the state machine completes successfully, `builder.SetResult()` is called, with the method return value if any. If an exception is thrown in the state machine, `builder.SetException(exception)` is called.

If the state machine reaches an `await expr` expression, `expr.GetAwaiter()` is invoked. If the awaiter implements `ICriticalNotifyCompletion` and `IsCompleted` is false, the state machine invokes `builder.AwaitUnsafeOnCompleted(ref awaiter, ref stateMachine)`. `AwaitUnsafeOnCompleted()` should call `awaiter.UnsafeOnCompleted(action)` with an `Action` that calls `stateMachine.MoveNext()` when the awaiter completes. Similarly for `INotifyCompletion` and `builder.AwaitOnCompleted()`.

`SetStateMachine(IAsyncStateMachine)` is called by the compiler-generated `IAsyncStateMachine` implementation. That can be used to identify the instance of the builder associated with a state machine instance, particularly for cases where the state machine is implemented as a value type: if the builder calls `stateMachine.SetStateMachine(stateMachine)`, the `stateMachine` will call `builder.SetStateMachine(stateMachine)` on the *builder instance associated with* `stateMachine`.

Overload Resolution

Overload resolution is extended to recognize *task types* in addition to `Task` and `Task<T>`.

An `async` lambda with no return value is an exact match for an overload candidate parameter of non-generic *task type*, and an `async` lambda with return type `T` is an exact match for an overload candidate parameter of

generic *task type*.

Otherwise if an `async` lambda is not an exact match for either of two candidate parameters of *task types*, or an exact match for both, and there is an implicit conversion from one candidate type to the other, the from candidate wins. Otherwise recursively evaluate the types `A` and `B` within `Task1<A>` and `Task2` for better match.

Otherwise if an `async` lambda is not an exact match for either of two candidate parameters of *task types*, but one candidate is a more specialized type than the other, the more specialized candidate wins.

Async Main

12/28/2021 • 2 minutes to read • [Edit Online](#)

Summary

Allow `await` to be used in an application's Main / entrypoint method by allowing the entrypoint to return `Task` / `Task<int>` and be marked `async`.

Motivation

It is very common when learning C#, when writing console-based utilities, and when writing small test apps to want to call and `await` `async` methods from Main. Today we add a level of complexity here by forcing such `await` 'ing to be done in a separate async method, which causes developers to need to write boilerplate like the following just to get started:

```
public static void Main()
{
    MainAsync().GetAwaiter().GetResult();
}

private static async Task MainAsync()
{
    ... // Main body here
}
```

We can remove the need for this boilerplate and make it easier to get started simply by allowing Main itself to be `async` such that `await` s can be used in it.

Detailed design

The following signatures are currently allowed entrypoints:

```
static void Main()
static void Main(string[])
static int Main()
static int Main(string[])
```

We extend the list of allowed entrypoints to include:

```
static Task Main()
static Task<int> Main()
static Task Main(string[])
static Task<int> Main(string[])
```

To avoid compatibility risks, these new signatures will only be considered as valid entrypoints if no overloads of the previous set are present. The language / compiler will not require that the entrypoint be marked as `async`, though we expect the vast majority of uses will be marked as such.

When one of these is identified as the entrypoint, the compiler will synthesize an actual entrypoint method that calls one of these coded methods:

- `static Task Main()` will result in the compiler emitting the equivalent of

```
private static void $GeneratedMain() => Main().GetAwaiter().GetResult();
```

- `static Task Main(string[])` will result in the compiler emitting the equivalent of

```
private static void $GeneratedMain(string[] args) => Main(args).GetAwaiter().GetResult();
```
- `static Task<int> Main()` will result in the compiler emitting the equivalent of

```
private static int $GeneratedMain() => Main().GetAwaiter().GetResult();
```
- `static Task<int> Main(string[])` will result in the compiler emitting the equivalent of

```
private static int $GeneratedMain(string[] args) => Main(args).GetAwaiter().GetResult();
```

Example usage:

```
using System;
using System.Net.Http;

class Test
{
    static async Task Main(string[] args) =>
        Console.WriteLine(await new HttpClient().GetStringAsync(args[0]));
}
```

Drawbacks

The main drawback is simply the additional complexity of supporting additional entrypoint signatures.

Alternatives

Other variants considered:

Allowing `async void`. We need to keep the semantics the same for code calling it directly, which would then make it difficult for a generated entrypoint to call it (no Task returned). We could solve this by generating two other methods, e.g.

```
public static async void Main()
{
    ... // await code
}
```

becomes

```
public static async void Main() => await $MainTask();

private static void $EntrypointMain() => Main().GetAwaiter().GetResult();

private static async Task $MainTask()
{
    ... // await code
}
```

There are also concerns around encouraging usage of `async void`.

Using "MainAsync" instead of "Main" as the name. While the async suffix is recommended for Task-returning methods, that's primarily about library functionality, which Main is not, and supporting additional entrypoint names beyond "Main" is not worth it.

Target-typed "default" literal

12/28/2021 • 2 minutes to read • [Edit Online](#)

Summary

The target-typed `default` feature is a shorter form variation of the `default(T)` operator, which allows the type to be omitted. Its type is inferred by target-typing instead. Aside from that, it behaves like `default(T)`.

Motivation

The main motivation is to avoid typing redundant information.

For instance, when invoking `void Method(ImmutableArray<SomeType> array)`, the *default* literal allows `M(default)` in place of `M(default(ImmutableArray<SomeType>))`.

This is applicable in a number of scenarios, such as:

- declaring locals (`ImmutableArray<SomeType> x = default;`)
- ternary operations (`var x = flag ? default : ImmutableArray<SomeType>.Empty;`)
- returning in methods and lambdas (`return default;`)
- declaring default values for optional parameters (`void Method(ImmutableArray<SomeType> arrayOpt = default)`)
- including default values in array creation expressions (`var x = new[] { default, ImmutableArray.Create(y) };`)

Detailed design

A new expression is introduced, the *default* literal. An expression with this classification can be implicitly converted to any type, by a *default literal conversion*.

The inference of the type for the *default* literal works the same as that for the *null* literal, except that any type is allowed (not just reference types).

This conversion produces the default value of the inferred type.

The *default* literal may have a constant value, depending on the inferred type. So `const int x = default;` is legal, but `const int? y = default;` is not.

The *default* literal can be the operand of equality operators, as long as the other operand has a type. So `default == x` and `x == default` are valid expressions, but `default == default` is illegal.

Drawbacks

A minor drawback is that *default* literal can be used in place of *null* literal in most contexts. Two of the exceptions are `throw null;` and `null == null`, which are allowed for the *null* literal, but not the *default* literal.

Alternatives

There are a couple of alternatives to consider:

- The status quo: The feature is not justified on its own merits and developers continue to use the default operator with an explicit type.
- Extending the null literal: This is the VB approach with `Nothing`. We could allow `int x = null;`.

Unresolved questions

- [x] Should *default* be allowed as the operand of the *is* or *as* operators? Answer: disallow `default is T`, allow `x is default`, allow `default as RefType` (with always-null warning)

Infer tuple names (aka. tuple projection initializers)

12/28/2021 • 2 minutes to read • [Edit Online](#)

Summary

In a number of common cases, this feature allows the tuple element names to be omitted and instead be inferred. For instance, instead of typing `(f1: x.f1, f2: x?.f2)`, the element names "f1" and "f2" can be inferred from `(x.f1, x?.f2)`.

This parallels the behavior of anonymous types, which allow inferring member names during creation. For instance, `new { x.f1, y?.f2 }` declares members "f1" and "f2".

This is particularly handy when using tuples in LINQ:

```
// "c" and "result" have element names "f1" and "f2"
var result = list.Select(c => (c.f1, c.f2)).Where(t => t.f2 == 1);
```

Detailed design

There are two parts to the change:

1. Try to infer a candidate name for each tuple element which does not have an explicit name:
 - Using same rules as name inference for anonymous types.
 - In C#, this allows three cases: `y` (identifier), `x.y` (simple member access) and `x?.y` (conditional access).
 - In VB, this allows for additional cases, such as `x.y()`.
 - Rejecting reserved tuple names (case-sensitive in C#, case-insensitive in VB), as they are either forbidden or already implicit. For instance, such as `ItemN`, `Rest`, and `Tostring`.
 - If any candidate names are duplicates (case-sensitive in C#, case-insensitive in VB) within the entire tuple, we drop those candidates,
2. During conversions (which check and warn about dropping names from tuple literals), inferred names would not produce any warnings. This avoids breaking existing tuple code.

Note that the rule for handling duplicates is different than that for anonymous types. For instance, `new { x.f1, x.f1 }` produces an error, but `(x.f1, x.f1)` would still be allowed (just without any inferred names). This avoids breaking existing tuple code.

For consistency, the same would apply to tuples produced by deconstruction-assignments (in C#):

```
// tuple has element names "f1" and "f2"
var tuple = ((x.f1, x?.f2) = (1, 2));
```

The same would also apply to VB tuples, using the VB-specific rules for inferring name from expression and case-insensitive name comparisons.

When using the C# 7.1 compiler (or later) with language version "7.0", the element names will be inferred (despite the feature not being available), but there will be a use-site error for trying to access them. This will limit additions of new code that would later face the compatibility issue (described below).

Drawbacks

The main drawback is that this introduces a compatibility break from C# 7.0:

```
Action y = () => M();  
var t = (x: x, y);  
t.y(); // this might have previously picked up an extension method called "y", but would now call the  
lambda.
```

The compatibility council found this break acceptable, given that it is limited and the time window since tuples shipped (in C# 7.0) is short.

pattern-matching with generics

12/28/2021 • 2 minutes to read • [Edit Online](#)

Summary

The specification for the [existing C# as operator](#) permits there to be no conversion between the type of the operand and the specified type when either is an open type. However, in C# 7 the `Type identifier` pattern requires there be a conversion between the type of the input and the given type.

We propose to relax this and change `expression is Type identifier`, in addition to being permitted in the conditions when it is permitted in C# 7, to also be permitted when `expression as Type` would be allowed. Specifically, the new cases are cases where the type of the expression or the specified type is an open type.

Motivation

Cases where pattern-matching should "obviously" be permitted currently fail to compile. See, for example, <https://github.com/dotnet/roslyn/issues/16195>.

Detailed design

We change the paragraph in the pattern-matching specification (the proposed addition is shown in bold):

Certain combinations of static type of the left-hand-side and the given type are considered incompatible and result in compile-time error. A value of static type `E` is said to be *pattern compatible* with the type `T` if there exists an identity conversion, an implicit reference conversion, a boxing conversion, an explicit reference conversion, or an unboxing conversion from `E` to `T`, **or if either `E` or `T` is an open type**. It is a compile-time error if an expression of type `E` is not pattern compatible with the type in a type pattern that it is matched with.

Drawbacks

None.

Alternatives

None.

Unresolved questions

None.

Design meetings

LDM considered this question and felt it was a bug-fix level change. We are treating it as a separate language feature because just making the change after the language has been released would introduce a forward incompatibility. Using the proposed change requires that the programmer specify language version 7.1.

Readonly references

12/28/2021 • 24 minutes to read • [Edit Online](#)

Summary

The "readonly references" feature is actually a group of features that leverage the efficiency of passing variables by reference, but without exposing the data to modifications:

- `in` parameters
- `ref readonly` returns
- `readonly` structs
- `ref / in` extension methods
- `ref readonly` locals
- `ref` conditional expressions

Passing arguments as readonly references.

There is an existing proposal that touches this topic <https://github.com/dotnet/roslyn/issues/115> as a special case of readonly parameters without going into many details. Here I just want to acknowledge that the idea by itself is not very new.

Motivation

Prior to this feature C# did not have an efficient way of expressing a desire to pass struct variables into method calls for readonly purposes with no intention of modifying. Regular by-value argument passing implies copying, which adds unnecessary costs. That drives users to use by-ref argument passing and rely on comments/documentation to indicate that the data is not supposed to be mutated by the callee. It is not a good solution for many reasons.

The examples are numerous - vector/matrix math operators in graphics libraries like [XNA](#) are known to have ref operands purely because of performance considerations. There is code in Roslyn compiler itself that uses structs to avoid allocations and then passes them by reference to avoid copying costs.

Solution (`in` parameters)

Similarly to the `out` parameters, `in` parameters are passed as managed references with additional guarantees from the callee.

Unlike `out` parameters which *must* be assigned by the callee before any other use, `in` parameters cannot be assigned by the callee at all.

As a result `in` parameters allow for effectiveness of indirect argument passing without exposing arguments to mutations by the callee.

Declaring `in` parameters

`in` parameters are declared by using `in` keyword as a modifier in the parameter signature.

For all purposes the `in` parameter is treated as a `readonly` variable. Most of the restrictions on the use of `in` parameters inside the method are the same as with `readonly` fields.

Indeed an `in` parameter may represent a `readonly` field. Similarity of restrictions is not a coincidence.

For example fields of an `in` parameter which has a struct type are all recursively classified as `readonly`

variables .

```
static Vector3 Add (in Vector3 v1, in Vector3 v2)
{
    // not OK!!
    v1 = default(Vector3);

    // not OK!!
    v1.X = 0;

    // not OK!!
    foo(ref v1.X);

    // OK
    return new Vector3(v1.X + v2.X, v1.Y + v2.Y, v1.Z + v2.Z);
}
```

- `in` parameters are allowed anywhere where ordinary byval parameters are allowed. This includes indexers, operators (including conversions), delegates, lambdas, local functions.

```
(in int x) => x // lambda expression
TValue this[in TKey index]; // indexer
public static Vector3 operator +(in Vector3 x, in Vector3 y) => ... // operator
```

- `in` is not allowed in combination with `out` or with anything that `out` does not combine with.
- It is not permitted to overload on `ref` / `out` / `in` differences.
- It is permitted to overload on ordinary byval and `in` differences.
- For the purpose of OHI (Overloading, Hiding, Implementing), `in` behaves similarly to an `out` parameter. All the same rules apply. For example the overriding method will have to match `in` parameters with `in` parameters of an identity-convertible type.
- For the purpose of delegate/lambda/method group conversions, `in` behaves similarly to an `out` parameter. Lambdas and applicable method group conversion candidates will have to match `in` parameters of the target delegate with `in` parameters of an identity-convertible type.
- For the purpose of generic variance, `in` parameters are nonvariant.

NOTE: There are no warnings on `in` parameters that have reference or primitives types. It may be pointless in general, but in some cases user must/want to pass primitives as `in`. Examples - overriding a generic method like `Method(in T param)` when `T` was substituted to be `int`, or when having methods like `Volatile.Read(in int location)`

It is conceivable to have an analyzer that warns in cases of inefficient use of `in` parameters, but the rules for such analysis would be too fuzzy to be a part of a language specification.

Use of `in` at call sites. (`in` arguments)

There are two ways to pass arguments to `in` parameters.

`in` arguments can match `in` parameters:

An argument with an `in` modifier at the call site can match `in` parameters.

```

int x = 1;

void M1<T>(in T x)
{
    // . . .
}

var x = M1(in x); // in argument to a method

class D
{
    public string this[in Guid index];
}

D dictionary = . . . ;
var y = dictionary[in Guid.Empty]; // in argument to an indexer

```

- `in` argument must be a *readable* LValue(*). Example: `M1(in 42)` is invalid

(*) The notion of LValue/RValue vary between languages.

Here, by LValue I mean an expression that represent a location that can be referred to directly. And RValue means an expression that yields a temporary result which does not persist on its own.

- In particular it is valid to pass `readonly` fields, `in` parameters or other formally `readonly` variables as `in` arguments. Example: `dictionary[in Guid.Empty]` is legal. `Guid.Empty` is a static readonly field.
- `in` argument must have type *identity-convertible* to the type of the parameter. Example: `M1<object>(in Guid.Empty)` is invalid. `Guid.Empty` is not *identity-convertible* to `object`

The motivation for the above rules is that `in` arguments guarantee *aliasing* of the argument variable. The callee always receives a direct reference to the same location as represented by the argument.

- in rare situations when `in` arguments must be stack-spilled due to `await` expressions used as operands of the same call, the behavior is the same as with `out` and `ref` arguments - if the variable cannot be spilled in referentially-transparent manner, an error is reported.

Examples:

1. `M1(in staticField, await SomethingAsync())` is valid. `staticField` is a static field which can be accessed more than once without observable side effects. Therefore both the order of side effects and aliasing requirements can be provided.
2. `M1(in RefReturningMethod(), await SomethingAsync())` will produce an error. `RefReturningMethod()` is a `ref` returning method. A method call may have observable side effects, therefore it must be evaluated before the `SomethingAsync()` operand. However the result of the invocation is a reference that cannot be preserved across the `await` suspension point which make the direct reference requirement impossible.

NOTE: the stack spilling errors are considered to be implementation-specific limitations. Therefore they do not have effect on overload resolution or lambda inference.

Ordinary byval arguments can match `in` parameters:

Regular arguments without modifiers can match `in` parameters. In such case the arguments have the same relaxed constraints as an ordinary byval arguments would have.

The motivation for this scenario is that `in` parameters in APIs may result in inconveniences for the user when arguments cannot be passed as a direct reference - ex: literals, computed or `await`-ed results or arguments that happen to have more specific types.

All these cases have a trivial solution of storing the argument value in a temporary local of appropriate type and passing that local as an `in` argument.

To reduce the need for such boilerplate code compiler can perform the same transformation, if needed, when `in` modifier is not present at the call site.

In addition, in some cases, such as invocation of operators, or `in` extension methods, there is no syntactical way to specify `in` at all. That alone requires specifying the behavior of ordinary byval arguments when they match `in` parameters.

In particular:

- it is valid to pass RValues. A reference to a temporary is passed in such case. Example:

```
Print("hello");           // not an error.

void Print<T>(in T x)
{
    // . . .
}
```

- implicit conversions are allowed.

This is actually a special case of passing an RValue

A reference to a temporary holding converted value is passed in such case. Example:

```
Print<int>(Short.MaxValue)    // not an error.
```

- in a case of a receiver of an `in` extension method (as opposed to `ref` extension methods), RValues or implicit *this-argument-conversions* are allowed. A reference to a temporary holding converted value is passed in such case. Example:

```
public static IEnumerable<T> Concat<T>(in this (IEnumerable<T>, IEnumerable<T>) arg) => . . .;

("aa", "bb").Concat<char>()    // not an error.
```

More information on `ref`/`in` extension methods is provided further in this document.

- argument spilling due to `await` operands could spill "by-value", if necessary. In scenarios where providing a direct reference to the argument is not possible due to intervening `await` a copy of the argument's value is spilled instead.

Example:

```
M1(RefReturningMethod(), await SomethingAsync())    // not an error.
```

Since the result of a side-effecting invocation is a reference that cannot be preserved across `await` suspension, a temporary containing the actual value will be preserved instead (as it would in an ordinary byval parameter case).

Omitted optional arguments

It is permitted for an `in` parameter to specify a default value. That makes the corresponding argument optional.

Omitting optional argument at the call site results in passing the default value via a temporary.

```
Print("hello");          // not an error, same as
Print("hello", c: Color.Black);

void Print(string s, in Color c = Color.Black)
{
    // . . .
}
```

Aliasing behavior in general

Just like `ref` and `out` variables, `in` variables are references/aliases to existing locations.

While callee is not allowed to write into them, reading an `in` parameter can observe different values as a side effect of other evaluations.

Example:

```
static Vector3 v = Vector3.Unity;

static void Main()
{
    Test(v);
}

static void Test(in Vector3 v1)
{
    Debug.Assert(v1 == Vector3.Unity);
    // changes v1 deterministically (no races required)
    ChangeV();
    Debug.Assert(v1 == Vector3.UnityX);
}

static void ChangeV()
{
    v = Vector3.UnityX;
}
```

`in` parameters and capturing of local variables.

For the purpose of lambda/async capturing `in` parameters behave the same as `out` and `ref` parameters.

- `in` parameters cannot be captured in a closure
- `in` parameters are not allowed in iterator methods
- `in` parameters are not allowed in async methods

Temporary variables.

Some uses of `in` parameter passing may require indirect use of a temporary local variable:

- `in` arguments are always passed as direct aliases when call-site uses `in`. Temporary is never used in such case.
- `in` arguments are not required to be direct aliases when call-site does not use `in`. When argument is not an LValue, a temporary may be used.
- `in` parameter may have default value. When corresponding argument is omitted at the call site, the default value are passed via a temporary.
- `in` arguments may have implicit conversions, including those that do not preserve identity. A temporary is used in those cases.
- receivers of ordinary struct calls may not be writeable LValues (**existing case!**). A temporary is used in those cases.

The life time of the argument temporaries matches the closest encompassing scope of the call-site.

The formal life time of temporary variables is semantically significant in scenarios involving escape analysis of variables returned by reference.

Metadata representation of `in` parameters.

When `System.Runtime.CompilerServices.IsReadOnlyAttribute` is applied to a byref parameter, it means that the parameter is an `in` parameter.

In addition, if the method is *abstract* or *virtual*, then the signature of such parameters (and only such parameters) must have `modreq[System.Runtime.InteropServices.InAttribute]`.

Motivation: this is done to ensure that in a case of method overriding/implementing the `in` parameters match.

Same requirements apply to `Invoke` methods in delegates.

Motivation: this is to ensure that existing compilers cannot simply ignore `readonly` when creating or assigning delegates.

Returning by readonly reference.

Motivation

The motivation for this sub-feature is roughly symmetrical to the reasons for the `in` parameters - avoiding copying, but on the returning side. Prior to this feature, a method or an indexer had two options: 1) return by reference and be exposed to possible mutations or 2) return by value which results in copying.

Solution (`ref readonly` returns)

The feature allows a member to return variables by reference without exposing them to mutations.

Declaring `ref readonly` returning members

A combination of modifiers `ref readonly` on the return signature is used to indicate that the member returns a readonly reference.

For all purposes a `ref readonly` member is treated as a `readonly` variable - similar to `readonly` fields and `in` parameters.

For example fields of `ref readonly` member which has a struct type are all recursively classified as `readonly` variables. - It is permitted to pass them as `in` arguments, but not as `ref` or `out` arguments.

```
ref readonly Guid Method1()
{
}

Method2(in Method1()); // valid. Can pass as `in` argument.

Method3(ref Method1()); // not valid. Cannot pass as `ref` argument
```

- `ref readonly` returns are allowed in the same places where `ref` returns are allowed. This includes indexers, delegates, lambdas, local functions.
- It is not permitted to overload on `ref` / `ref readonly` / differences.
- It is permitted to overload on ordinary byval and `ref readonly` return differences.
- For the purpose of OHI (Overloading, Hiding, Implementing), `ref readonly` is similar but distinct from `ref`. For example the a method that overrides `ref readonly` one, must itself be `ref readonly` and have

identity-convertible type.

- For the purpose of delegate/lambda/method group conversions, `ref readonly` is similar but distinct from `ref`. Lambdas and applicable method group conversion candidates have to match `ref readonly` return of the target delegate with `ref readonly` return of the type that is identity-convertible.
- For the purpose of generic variance, `ref readonly` returns are nonvariant.

NOTE: There are no warnings on `ref readonly` returns that have reference or primitives types. It may be pointless in general, but in some cases user must/want to pass primitives as `in`. Examples - overriding a generic method like `ref readonly T Method()` when `T` was substituted to be `int`.

It is conceivable to have an analyzer that warns in cases of inefficient use of `ref readonly` returns, but the rules for such analysis would be too fuzzy to be a part of a language specification.

Returning from `ref readonly` members

Inside the method body the syntax is the same as with regular `ref` returns. The `readonly` will be inferred from the containing method.

The motivation is that `return ref readonly <expression>` is unnecessary long and only allows for mismatches on the `readonly` part that would always result in errors. The `ref` is, however, required for consistency with other scenarios where something is passed via strict aliasing vs. by value.

Unlike the case with `in` parameters, `ref readonly` returns never return via a local copy. Considering that the copy would cease to exist immediately upon returning such practice would be pointless and dangerous. Therefore `ref readonly` returns are always direct references.

Example:

```
struct ImmutableArray<T>
{
    private readonly T[] array;

    public ref readonly T ItemRef(int i)
    {
        // returning a readonly reference to an array element
        return ref this.array[i];
    }
}
```

- An argument of `return ref` must be an LValue (**existing rule**)
- An argument of `return ref` must be "safe to return" (**existing rule**)
- In a `ref readonly` member an argument of `return ref` is *not required to be writeable*. For example such member can `ref`-return a `readonly` field or one of its `in` parameters.

Safe to Return rules.

Normal safe to return rules for references will apply to `readonly` references as well.

Note that a `ref readonly` can be obtained from a regular `ref` local/parameter/return, but not the other way around. Otherwise the safety of `ref readonly` returns is inferred the same way as for regular `ref` returns.

Considering that RValues can be passed as `in` parameter and returned as `ref readonly` we need one more rule - **RValues are not safe-to-return by reference.**

Consider the situation when an RValue is passed to an `in` parameter via a copy and then returned back in a

form of a `ref readonly`. In the context of the caller the result of such invocation is a reference to local data and as such is unsafe to return. Once RValues are not safe to return, the existing rule `#6` already handles this case.

Example:

```
ref readonly Vector3 Test1()
{
    // can pass an RValue as "in" (via a temp copy)
    // but the result is not safe to return
    // because the RValue argument was not safe to return by reference
    return ref Test2(default(Vector3));
}

ref readonly Vector3 Test2(in Vector3 r)
{
    // this is ok, r is returnable
    return ref r;
}
```

Updated `safe to return` rules:

1. **refs to variables on the heap are safe to return**
2. **ref/in parameters are safe to return** `in` parameters naturally can only be returned as readonly.
3. **out parameters are safe to return** (but must be definitely assigned, as is already the case today)
4. **instance struct fields are safe to return as long as the receiver is safe to return**
5. **'this' is not safe to return from struct members**
6. **a ref, returned from another method is safe to return if all refs/outs passed to that method as formal parameters were safe to return.** *Specifically it is irrelevant if receiver is safe to return, regardless whether receiver is a struct, class or typed as a generic type parameter.*
7. **RValues are not safe to return by reference.** *Specifically RValues are safe to pass as in parameters.*

NOTE: There are additional rules regarding safety of returns that come into play when ref-like types and ref-reassignments are involved. The rules equally apply to `ref` and `ref readonly` members and therefore are not mentioned here.

Aliasing behavior.

`ref readonly` members provide the same aliasing behavior as ordinary `ref` members (except for being readonly). Therefore for the purpose of capturing in lambdas, async, iterators, stack spilling etc... the same restrictions apply. - I.E. due to inability to capture the actual references and due to side-effecting nature of member evaluation such scenarios are disallowed.

It is permitted and required to make a copy when `ref readonly` return is a receiver of regular struct methods, which take `this` as an ordinary writeable reference. Historically in all cases where such invocations are applied to readonly variable a local copy is made.

Metadata representation.

When `System.Runtime.CompilerServices.IsReadOnlyAttribute` is applied to the return of a byref returning method, it means that the method returns a readonly reference.

In addition, the result signature of such methods (and only those methods) must have

```
modreq[System.Runtime.CompilerServices.IsReadOnlyAttribute].
```

Motivation: this is to ensure that existing compilers cannot simply ignore `readonly` when invoking methods

with `ref readonly` returns

Readonly structs

In short - a feature that makes `this` parameter of all instance members of a struct, except for constructors, an `in` parameter.

Motivation

Compiler must assume that any method call on a struct instance may modify the instance. Indeed a writeable reference is passed to the method as `this` parameter and fully enables this behavior. To allow such invocations on `readonly` variables, the invocations are applied to temp copies. That could be unintuitive and sometimes forces people to abandon `readonly` for performance reasons.

Example: <https://codeblog.jonskeet.uk/2014/07/16/micro-optimization-the-surprising-inefficiency-of-readonly-fields/>

After adding support for `in` parameters and `ref readonly` returns the problem of defensive copying will get worse since readonly variables will become more common.

Solution

Allow `readonly` modifier on struct declarations which would result in `this` being treated as `in` parameter on all struct instance methods except for constructors.

```
static void Test(in Vector3 v1)
{
    // no need to make a copy of v1 since Vector3 is a readonly struct
    System.Console.WriteLine(v1.ToString());
}

readonly struct Vector3
{
    . . .

    public override string ToString()
    {
        // not OK!! `this` is an `in` parameter
        foo(ref this.X);

        // OK
        return $"X: {X}, Y: {Y}, Z: {Z}";
    }
}
```

Restrictions on members of readonly struct

- Instance fields of a readonly struct must be readonly.
Motivation: can only be written to externally, but not through members.
- Instance autoproperties of a readonly struct must be get-only.
Motivation: consequence of restriction on instance fields.
- Readonly struct may not declare field-like events.
Motivation: consequence of restriction on instance fields.

Metadata representation.

When `System.Runtime.CompilerServices.IsReadOnlyAttribute` is applied to a value type, it means that the type is a `readonly struct`.

In particular:

- The identity of the `IsReadOnlyAttribute` type is unimportant. In fact it can be embedded by the compiler in

the containing assembly if needed.

ref / in extension methods

There is actually an existing proposal (<https://github.com/dotnet/roslyn/issues/165>) and corresponding prototype PR (<https://github.com/dotnet/roslyn/pull/15650>). I just want to acknowledge that this idea is not entirely new. It is, however, relevant here since `ref readonly` elegantly removes the most contentious issue about such methods - what to do with RValue receivers.

The general idea is allowing extension methods to take the `this` parameter by reference, as long as the type is known to be a struct type.

```
public static void Extension(ref this Guid self)
{
    // do something
}
```

The reasons for writing such extension methods are primarily:

1. Avoid copying when receiver is a large struct
2. Allow mutating extension methods on structs

The reasons why we do not want to allow this on classes

1. It would be of very limited purpose.
2. It would break long standing invariant that a method call cannot turn non-`null` receiver to become `null` after invocation.

In fact, currently a non-`null` variable cannot become `null` unless *explicitly* assigned or passed by `ref` or `out`. That greatly aids readability or other forms of "can this be a null here" analysis. 3. It would be hard to reconcile with "evaluate once" semantics of null-conditional accesses. Example:

`obj.stringField?.RefExtension(...)` - need to capture a copy of `stringField` to make the null check meaningful, but then assignments to `this` inside `RefExtension` would not be reflected back to the field.

An ability to declare extension methods on **structs** that take the first argument by reference was a long-standing request. One of the blocking consideration was "what happens if receiver is not an LValue?".

- There is a precedent that any extension method could also be called as a static method (sometimes it is the only way to resolve ambiguity). It would dictate that RValue receivers should be disallowed.
- On the other hand there is a practice of making invocation on a copy in similar situations when struct instance methods are involved.

The reason why the "implicit copying" exists is because the majority of struct methods do not actually modify the struct while not being able to indicate that. Therefore the most practical solution was to just make the invocation on a copy, but this practice is known for harming performance and causing bugs.

Now, with availability of `in` parameters, it is possible for an extension to signal the intent. Therefore the conundrum can be resolved by requiring `ref` extensions to be called with writeable receivers while `in` extensions permit implicit copying if necessary.

```
// this can be called on either RValue or an LValue
public static void Reader(in this Guid self)
{
    // do something nonmutating.
    WriteLine(self == default(Guid));
}

// this can be called only on an LValue
public static void Mutator(ref this Guid self)
{
    // can mutate self
    self = new Guid();
}
```

in **extensions and generics.**

The purpose of `ref` extension methods is to mutate the receiver directly or by invoking mutating members. Therefore `ref this T` extensions are allowed as long as `T` is constrained to be a struct.

On the other hand `in` extension methods exist specifically to reduce implicit copying. However any use of an `in T` parameter will have to be done through an interface member. Since all interface members are considered mutating, any such use would require a copy. - Instead of reducing copying, the effect would be the opposite. Therefore `in this T` is not allowed when `T` is a generic type parameter regardless of constraints.

Valid kinds of extension methods (recap):

The following forms of `this` declaration in an extension method are now allowed:

1. `this T arg` - regular byval extension. (existing case)
 - T can be any type, including reference types or type parameters. Instance will be the same variable after the call. Allows implicit conversions of *this-argument-conversion* kind. Can be called on RValues.
 - `in this T self` - `in` extension. T must be an actual struct type. Instance will be the same variable after the call. Allows implicit conversions of *this-argument-conversion* kind. Can be called on RValues (may be invoked on a temp if needed).
 - `ref this T self` - `ref` extension. T must be a struct type or a generic type parameter constrained to be a struct. Instance may be written to by the invocation. Allows only identity conversions. Must be called on writeable LValue. (never invoked via a temp).

Readonly ref locals.

Motivation.

Once `ref readonly` members were introduced, it was clear from the use that they need to be paired with appropriate kind of local. Evaluation of a member may produce or observe side effects, therefore if the result must be used more than once, it needs to be stored. Ordinary `ref` locals do not help here since they cannot be assigned a `readonly` reference.

Solution.

Allow declaring `ref readonly` locals. This is a new kind of `ref` locals that is not writeable. As a result `ref readonly` locals can accept references to readonly variables without exposing these variables to writes.

Declaring and using `ref readonly` locals.

The syntax of such locals uses `ref readonly` modifiers at declaration site (in that specific order). Similarly to ordinary `ref` locals, `ref readonly` locals must be ref-initialized at declaration. Unlike regular `ref` locals, `ref readonly` locals can refer to `readonly` LValues like `in` parameters, `readonly` fields, `ref readonly`

methods.

For all purposes a `ref readonly` local is treated as a `readonly` variable. Most of the restrictions on the use are the same as with `readonly` fields or `in` parameters.

For example fields of an `in` parameter which has a struct type are all recursively classified as `readonly` variables .

```
static readonly ref Vector3 M1() => . . .

static readonly ref Vector3 M1_Trace()
{
    // OK
    ref readonly var r1 = ref M1();

    // Not valid. Need an LValue
    ref readonly Vector3 r2 = ref default(Vector3);

    // Not valid. r1 is readonly.
    Mutate(ref r1);

    // OK.
    Print(in r1);

    // OK.
    return ref r1;
}
```

Restrictions on use of `ref readonly` locals

Except for their `readonly` nature, `ref readonly` locals behave like ordinary `ref` locals and are subject to exactly same restrictions.

For example restrictions related to capturing in closures, declaring in `async` methods or the `safe-to-return` analysis equally applies to `ref readonly` locals.

Ternary `ref` expressions. (aka "Conditional LValues")

Motivation

Use of `ref` and `ref readonly` locals exposed a need to ref-initialize such locals with one or another target variable based on a condition.

A typical workaround is to introduce a method like:

```
ref T Choice(bool condition, ref T consequence, ref T alternative)
{
    if (condition)
    {
        return ref consequence;
    }
    else
    {
        return ref alternative;
    }
}
```

Note that `Choice` is not an exact replacement of a ternary since *all* arguments must be evaluated at the call site, which was leading to unintuitive behavior and bugs.

The following will not work as expected:

```
// will crash with NRE because 'arr[0]' will be executed unconditionally
ref var r = ref Choice(arr != null, ref arr[0], ref otherArr[0]);
```

Solution

Allow special kind of conditional expression that evaluates to a reference to one of LValue argument based on a condition.

Using `ref` **ternary expression**.

The syntax for the `ref` flavor of a conditional expression is

```
<condition> ? ref <consequence> : ref <alternative>;
```

Just like with the ordinary conditional expression only `<consequence>` or `<alternative>` is evaluated depending on result of the boolean condition expression.

Unlike ordinary conditional expression, `ref` conditional expression:

- requires that `<consequence>` and `<alternative>` are LValues.
- `ref` conditional expression itself is an LValue and
- `ref` conditional expression is writeable if both `<consequence>` and `<alternative>` are writeable LValues

Examples:

`ref` ternary is an LValue and as such it can be passed/assigned/returned by reference;

```
// pass by reference
foo(ref (arr != null ? ref arr[0]: ref otherArr[0]));

// return by reference
return ref (arr != null ? ref arr[0]: ref otherArr[0]);
```

Being an LValue, it can also be assigned to.

```
// assign to
(arr != null ? ref arr[0]: ref otherArr[0]) = 1;

// error. readOnlyField is readonly and thus conditional expression is readonly
(arr != null ? ref arr[0]: ref obj.readOnlyField) = 1;
```

Can be used as a receiver of a method call and skip copying if necessary.

```
// no copies
(arr != null ? ref arr[0]: ref otherArr[0]).StructMethod();

// invoked on a copy.
// The receiver is `readonly` because readOnlyField is readonly.
(arr != null ? ref arr[0]: ref obj.readOnlyField).StructMethod();

// no copies. `ReadOnlyStructMethod` is a method on a `readonly` struct
// and can be invoked directly on a readonly receiver
(arr != null ? ref arr[0]: ref obj.readOnlyField).ReadOnlyStructMethod();
```

`ref` ternary can be used in a regular (not ref) context as well.

```
// only an example
// a regular ternary could work here just the same
int x = (arr != null ? ref arr[0]: ref otherArr[0]);
```

Drawbacks

I can see two major arguments against enhanced support for references and readonly references:

1. The problems that are solved here are very old. Why suddenly solve them now, especially since it would not help existing code?

As we find C# and .Net used in new domains, some problems become more prominent.

As examples of environments that are more critical than average about computation overheads, I can list

- cloud/datacenter scenarios where computation is billed for and responsiveness is a competitive advantage.
- Games/VR/AR with soft-realtime requirements on latencies

This feature does not sacrifice any of the existing strengths such as type-safety, while allowing to lower overheads in some common scenarios.

2. Can we reasonably guarantee that the callee will play by the rules when it opts into `readonly` contracts?

We have similar trust when using `out`. Incorrect implementation of `out` can cause unspecified behavior, but in reality it rarely happens.

Making the formal verification rules familiar with `ref readonly` would further mitigate the trust issue.

Alternatives

The main competing design is really "do nothing".

Compile time enforcement of safety for ref-like types

12/28/2021 • 16 minutes to read • [Edit Online](#)

Introduction

The main reason for the additional safety rules when dealing with types like `Span<T>` and `ReadOnlySpan<T>` is that such types must be confined to the execution stack.

There are two reasons why `Span<T>` and similar types must be a stack-only types.

1. `Span<T>` is semantically a struct containing a reference and a range - `(ref T data, int length)`. Regardless of actual implementation, writes to such struct would not be atomic. Concurrent "tearing" of such struct would lead to the possibility of `length` not matching the `data`, causing out-of-range accesses and type-safety violations, which ultimately could result in GC heap corruption in seemingly "safe" code.
2. Some implementations of `Span<T>` literally contain a managed pointer in one of its fields. Managed pointers are not supported as fields of heap objects and code that manages to put a managed pointer on the GC heap typically crashes at JIT time.

All the above problems would be alleviated if instances of `Span<T>` are constrained to exist only on the execution stack.

An additional problem arises due to composition. It would be generally desirable to build more complex data types that would embed `Span<T>` and `ReadOnlySpan<T>` instances. Such composite types would have to be structs and would share all the hazards and requirements of `Span<T>`. As a result the safety rules described here should be viewed as applicable to the whole range of *ref-like types*.

The [draft language specification](#) is intended to ensure that values of a ref-like type occur only on the stack.

Generalized `ref-like` types in source code

`ref-like` structs are explicitly marked in the source code using `ref` modifier:

```
ref struct TwoSpans<T>
{
    // can have ref-like instance fields
    public Span<T> first;
    public Span<T> second;
}

// error: arrays of ref-like types are not allowed.
TwoSpans<T>[] arr = null;
```

Designating a struct as ref-like will allow the struct to have ref-like instance fields and will also make all the requirements of ref-like types applicable to the struct.

Metadata representation of ref-like structs

Ref-like structs will be marked with `System.Runtime.CompilerServices.IsRefLikeAttribute` attribute.

The attribute will be added to common base libraries such as `mscorlib`. In a case if the attribute is not available,

compiler will generate an internal one similarly to other embedded-on-demand attributes such as

`IsReadOnlyAttribute`.

An additional measure will be taken to prevent the use of ref-like structs in compilers not familiar with the safety rules (this includes C# compilers prior to the one in which this feature is implemented).

Having no other good alternatives that work in old compilers without servicing, an `Obsolete` attribute with a known string will be added to all ref-like structs. Compilers that know how to use ref-like types will ignore this particular form of `Obsolete`.

A typical metadata representation:

```
[IsRefLike]
[Obsolete("Types with embedded references are not supported in this version of your compiler.")]
public struct TwoSpans<T>
{
    // . . . .
}
```

NOTE: it is not the goal to make it so that any use of ref-like types on old compilers fails 100%. That is hard to achieve and is not strictly necessary. For example there would always be a way to get around the `Obsolete` using dynamic code or, for example, creating an array of ref-like types through reflection.

In particular, if user wants to actually put an `Obsolete` or `Deprecated` attribute on a ref-like type, we will have no choice other than not emitting the predefined one since `Obsolete` attribute cannot be applied more than once..

Examples:

```

SpanLikeType M1(ref SpanLikeType x, Span<byte> y)
{
    // this is all valid, unconcerned with stack-referring stuff
    var local = new SpanLikeType(y);
    x = local;
    return x;
}

void Test1(ref SpanLikeType param1, Span<byte> param2)
{
    Span<byte> stackReferring1 = stackalloc byte[10];
    var stackReferring2 = new SpanLikeType(stackReferring1);

    // this is allowed
    stackReferring2 = M1(ref stackReferring2, stackReferring1);

    // this is NOT allowed
    stackReferring2 = M1(ref param1, stackReferring1);

    // this is NOT allowed
    param1 = M1(ref stackReferring2, stackReferring1);

    // this is NOT allowed
    param2 = stackReferring1.Slice(10);

    // this is allowed
    param1 = new SpanLikeType(param2);

    // this is allowed
    stackReferring2 = param1;
}

ref SpanLikeType M2(ref SpanLikeType x)
{
    return ref x;
}

ref SpanLikeType Test2(ref SpanLikeType param1, Span<byte> param2)
{
    Span<byte> stackReferring1 = stackalloc byte[10];
    var stackReferring2 = new SpanLikeType(stackReferring1);

    ref var stackReferring3 = M2(ref stackReferring2);

    // this is allowed
    stackReferring3 = M1(ref stackReferring2, stackReferring1);

    // this is allowed
    M2(ref stackReferring3) = stackReferring2;

    // this is NOT allowed
    M1(ref param1) = stackReferring2;

    // this is NOT allowed
    param1 = stackReferring3;

    // this is NOT allowed
    return ref stackReferring3;

    // this is allowed
    return ref param1;
}

```

Draft language specification

Below we describe a set of safety rules for ref-like types (`ref struct`s) to ensure that values of these types occur only on the stack. A different, simpler set of safety rules would be possible if locals cannot be passed by reference. This specification would also permit the safe reassignment of ref locals.

Overview

We associate with each expression at compile-time the concept of what scope that expression is permitted to escape to, "safe-to-escape". Similarly, for each lvalue we maintain a concept of what scope a reference to it is permitted to escape to, "ref-safe-to-escape". For a given lvalue expression, these may be different.

These are analogous to the "safe to return" of the ref locals feature, but it is more fine-grained. Where the "safe-to-return" of an expression records only whether (or not) it may escape the enclosing method as a whole, the safe-to-escape records which scope it may escape to (which scope it may not escape beyond). The basic safety mechanism is enforced as follows. Given an assignment from an expression E1 with a safe-to-escape scope S1, to an (lvalue) expression E2 with safe-to-escape scope S2, it is an error if S2 is a wider scope than S1. By construction, the two scopes S1 and S2 are in a nesting relationship, because a legal expression is always safe-to-return from some scope enclosing the expression.

For the time being it is sufficient, for the purpose of the analysis, to support just two scopes - external to the method, and top-level scope of the method. That is because ref-like values with inner scopes cannot be created and ref locals do not support re-assignment. The rules, however, can support more than two scope levels.

The precise rules for computing the *safe-to-return* status of an expression, and the rules governing the legality of expressions, follow.

ref-safe-to-escape

The *ref-safe-to-escape* is a scope, enclosing an lvalue expression, to which it is safe for a ref to the lvalue to escape to. If that scope is the entire method, we say that a ref to the lvalue is *safe to return* from the method.

safe-to-escape

The *safe-to-escape* is a scope, enclosing an expression, to which it is safe for the value to escape to. If that scope is the entire method, we say that the value is *safe to return* from the method.

An expression whose type is not a `ref struct` type is *safe-to-return* from the entire enclosing method. Otherwise we refer to the rules below.

Parameters

An lvalue designating a formal parameter is *ref-safe-to-escape* (by reference) as follows:

- If the parameter is a `ref`, `out`, or `in` parameter, it is *ref-safe-to-escape* from the entire method (e.g. by a `return ref` statement); otherwise
- If the parameter is the `this` parameter of a struct type, it is *ref-safe-to-escape* to the top-level scope of the method (but not from the entire method itself); [Sample](#)
- Otherwise the parameter is a value parameter, and it is *ref-safe-to-escape* to the top-level scope of the method (but not from the method itself).

An expression that is an rvalue designating the use of a formal parameter is *safe-to-escape* (by value) from the entire method (e.g. by a `return` statement). This applies to the `this` parameter as well.

Locals

An lvalue designating a local variable is *ref-safe-to-escape* (by reference) as follows:

- If the variable is a `ref` variable, then its *ref-safe-to-escape* is taken from the *ref-safe-to-escape* of its initializing expression; otherwise
- The variable is *ref-safe-to-escape* the scope in which it was declared.

An expression that is an rvalue designating the use of a local variable is *safe-to-escape* (by value) as follows:

- But the general rule above, a local whose type is not a `ref struct` type is *safe-to-return* from the entire enclosing method.
- If the variable is an iteration variable of a `foreach` loop, then the variable's *safe-to-escape* scope is the same as the *safe-to-escape* of the `foreach` loop's expression.
- A local of `ref struct` type and uninitialized at the point of declaration is *safe-to-return* from the entire enclosing method.
- Otherwise the variable's type is a `ref struct` type, and the variable's declaration requires an initializer. The variable's *safe-to-escape* scope is the same as the *safe-to-escape* of its initializer.

Field reference

An lvalue designating a reference to a field, `e.F`, is *ref-safe-to-escape* (by reference) as follows:

- If `e` is of a reference type, it is *ref-safe-to-escape* from the entire method; otherwise
- If `e` is of a value type, its *ref-safe-to-escape* is taken from the *ref-safe-to-escape* of `e`.

An rvalue designating a reference to a field, `e.F`, has a *safe-to-escape* scope that is the same as the *safe-to-escape* of `e`.

Operators including `?:`

The application of a user-defined operator is treated as a method invocation.

For an operator that yields an rvalue, such as `e1 + e2` or `c ? e1 : e2`, the *safe-to-escape* of the result is the narrowest scope among the *safe-to-escape* of the operands of the operator. As a consequence, for a unary operator that yields an rvalue, such as `+e`, the *safe-to-escape* of the result is the *safe-to-escape* of the operand.

For an operator that yields an lvalue, such as `c ? ref e1 : ref e2`

- the *ref-safe-to-escape* of the result is the narrowest scope among the *ref-safe-to-escape* of the operands of the operator.
- the *safe-to-escape* of the operands must agree, and that is the *safe-to-escape* of the resulting lvalue.

Method invocation

An lvalue resulting from a ref-returning method invocation `e1.M(e2, ...)` is *ref-safe-to-escape* the smallest of the following scopes:

- The entire enclosing method
- the *ref-safe-to-escape* of all `ref` and `out` argument expressions (excluding the receiver)
- For each `in` parameter of the method, if there is a corresponding expression that is an lvalue, its *ref-safe-to-escape*, otherwise the nearest enclosing scope
- the *safe-to-escape* of all argument expressions (including the receiver)

Note: the last bullet is necessary to handle code such as

```
var sp = new Span(...)  
return ref sp[0];
```

or

```
return ref M(sp, 0);
```

An rvalue resulting from a method invocation `e1.M(e2, ...)` is *safe-to-escape* from the smallest of the following scopes:

- The entire enclosing method
- the *safe-to-escape* of all argument expressions (including the receiver)

An Rvalue

An rvalue is *ref-safe-to-escape* from the nearest enclosing scope. This occurs for example in an invocation such as `M(ref d.Length)` where `d` is of type `dynamic`. It is also consistent with (and perhaps subsumes) our handling of arguments corresponding to `in` parameters.

Property invocations

A property invocation (either `get` or `set`) is treated as a method invocation of the underlying method by the above rules.

`stackalloc`

A `stackalloc` expression is an rvalue that is *safe-to-escape* to the top-level scope of the method (but not from the entire method itself).

Constructor invocations

A `new` expression that invokes a constructor obeys the same rules as a method invocation that is considered to return the type being constructed.

In addition *safe-to-escape* is no wider than the smallest of the *safe-to-escape* of all arguments/operands of the object initializer expressions, recursively, if initializer is present.

Span constructor

The language relies on `Span<T>` not having a constructor of the following form:

```
void Example(ref int x)
{
    // Create a span of length one
    var span = new Span<int>(ref x);
}
```

Such a constructor makes `Span<T>` which are used as fields indistinguishable from a `ref` field. The safety rules described in this document depend on `ref` fields not being a valid construct in C# or .NET.

`default` **expressions**

A `default` expression is *safe-to-escape* from the entire enclosing method.

Language Constraints

We wish to ensure that no `ref` local variable, and no variable of `ref struct` type, refers to stack memory or variables that are no longer alive. We therefore have the following language constraints:

- Neither a `ref` parameter, nor a `ref` local, nor a parameter or local of a `ref struct` type can be lifted into a lambda or local function.
- Neither a `ref` parameter nor a parameter of a `ref struct` type may be an argument on an iterator method or an `async` method.
- Neither a `ref` local, nor a local of a `ref struct` type may be in scope at the point of a `yield return` statement or an `await` expression.
- A `ref struct` type may not be used as a type argument, or as an element type in a tuple type.
- A `ref struct` type may not be the declared type of a field, except that it may be the declared type of an instance field of another `ref struct`.

- A `ref struct` type may not be the element type of an array.
- A value of a `ref struct` type may not be boxed:
 - There is no conversion from a `ref struct` type to the type `object` or the type `System.ValueType`.
 - A `ref struct` type may not be declared to implement any interface
 - No instance method declared in `object` or in `System.ValueType` but not overridden in a `ref struct` type may be called with a receiver of that `ref struct` type.
 - No instance method of a `ref struct` type may be captured by method conversion to a delegate type.
- For a ref reassignment `ref e1 = ref e2`, the *ref-safe-to-escape* of `e2` must be at least as wide a scope as the *ref-safe-to-escape* of `e1`.
- For a ref return statement `return ref e1`, the *ref-safe-to-escape* of `e1` must be *ref-safe-to-escape* from the entire method. (TODO: Do we also need a rule that `e1` must be *safe-to-escape* from the entire method, or is that redundant?)
- For a return statement `return e1`, the *safe-to-escape* of `e1` must be *safe-to-escape* from the entire method.
- For an assignment `e1 = e2`, if the type of `e1` is a `ref struct` type, then the *safe-to-escape* of `e2` must be at least as wide a scope as the *safe-to-escape* of `e1`.
- For a method invocation if there is a `ref` or `out` argument of a `ref struct` type (including the receiver unless the type is `readonly`), with *safe-to-escape* E1, then no argument (including the receiver) may have a narrower *safe-to-escape* than E1. [Sample](#)
- A local function or anonymous function may not refer to a local or parameter of `ref struct` type declared in an enclosing scope.

Open Issue: We need some rule that permits us to produce an error when needing to spill a stack value of a `ref struct` type at an await expression, for example in the code

```
Foo(new Span<int>(...), await e2);
```

Explanations

These explanations and samples help explain why many of the safety rules above exist

Method Arguments Must Match

When invoking a method where there is an `out` or `ref` parameter that is a `ref struct` then all of the `ref struct` parameters need to have the same lifetime. This is necessary because C# must make all of its decisions around lifetime safety based on the information available in the signature of the method and the lifetime of the values at the call site.

When there are `ref` parameters that are `ref struct` then there is the potential that they could swap around their contents. Hence at the call site we must ensure all of these **potential** swaps are compatible. If the language didn't enforce that then it will allow for bad code like the following.

```

void M1(ref Span<int> s1)
{
    Span<int> s2 = stackalloc int[1];
    Swap(ref s1, ref s2);
}

void Swap(ref Span<int> x, ref Span<int> y)
{
    // This will effectively assign the stackalloc to the s1 parameter and allow it
    // to escape to the caller of M1
    ref x = ref y;
}

```

This analysis of `ref` parameters includes the receiver in instance methods. This is necessary because it can be used to store values passed in as parameters, just as a `ref` parameter could. This means with mismatched lifetimes you could create a type safety hole in the following way:

```

ref struct S
{
    public Span<int> Span;

    public void Set(Span<int> span)
    {
        Span = span;
    }
}

void Broken(ref S s)
{
    Span<int> span = stackalloc int[1];

    // The result of a stackalloc is now stored in s.Span and escaped to the caller
    // of Broken
    s.Set(span);
}

```

For the purpose of this analysis the receiver is considered an `in`, not a `ref`, if the type is a `readonly struct`. In that case the receiver cannot be used to store values from other parameters, it is effectively an `in` parameter for analysis purposes. Hence the same example above is legal when `S` is `readonly` because the `span` cannot be stored anywhere.

Struct This Escape

When it comes to span safety rules, the `this` value in an instance member is modeled as a parameter to the member. Now for a `struct` the type of `this` is actually `ref S` where in a `class` it's simply `S` (for members of a `class / struct` named `S`).

Yet `this` has different escaping rules than other `ref` parameters. Specifically it is not ref-safe-to-escape while other parameters are:

```

ref struct S
{
    int Field;

    // Illegal because `this` isn't safe to escape as ref
    ref int Get() => ref Field;

    // Legal
    ref int GetParam(ref int p) => ref p;
}

```

The reason for this restriction actually has little to do with `struct` member invocation. There are some rules that need to be worked out with respect to member invocation on `struct` members where the receiver is an rvalue. But that is very approachable.

The reason for this restriction is actually about interface invocation. Specifically it comes down to whether or not the following sample should or should not compile;

```
interface I1
{
    ref int Get();
}

ref int Use<T>(T p)
    where T : I1
{
    return ref p.Get();
}
```

Consider the case where `T` is instantiated as a `struct`. If the `this` parameter is ref-safe-to-escape then the return of `p.Get` could point to the stack (specifically it could be a field inside of the instantiated type of `T`). That means the language could not allow this sample to compile as it could be returning a `ref` to a stack location. On the other hand if `this` is not ref-safe-to-escape then `p.Get` cannot refer to the stack and hence it's safe to return.

This is why the escapability of `this` in a `struct` is really all about interfaces. It can absolutely be made to work but it has a trade off. The design eventually came down in favor of making interfaces more flexible.

There is potential for us to relax this in the future though.

Future Considerations

Length one `Span<T>` over ref values

Though not legal today there are cases where creating a length one `Span<T>` instance over a value would be beneficial:

```
void RefExample()
{
    int x = ...;

    // Today creating a length one Span<int> requires a stackalloc and a new
    // local
    Span<int> span1 = stackalloc [ ] { x };
    Use(span1);
    x = span1[0];

    // Simpler to just allow length one span
    var span2 = new Span<int>(ref x);
    Use(span2);
}
```

This feature gets more compelling if we lift the restrictions on [fixed sized buffers](#) as it would allow for `Span<T>` instances of even greater length.

If there is ever a need to go down this path then the language could accommodate this by ensuring such `Span<T>` instances were downward facing only. That is they were only ever *safe-to-escape* to the scope in which they were created. This ensure the language never had to consider a `ref` value escaping a method via a `ref struct` return or field of `ref struct`. This would likely also require further changes to recognize such

constructors as capturing a `ref` parameter in this way though.

Non-trailing named arguments

12/28/2021 • 3 minutes to read • [Edit Online](#)

Summary

Allow named arguments to be used in non-trailing position, as long as they are used in their correct position.

For example: `DoSomething(isEmployed:true, name, age);`.

Motivation

The main motivation is to avoid typing redundant information. It is common to name an argument that is a literal (such as `null`, `true`) for the purpose of clarifying the code, rather than of passing arguments out-of-order. That is currently disallowed (`CS1738`) unless all the following arguments are also named.

```
DoSomething(isEmployed:true, name, age); // currently disallowed, even though all arguments are in position
// CS1738 "Named argument specifications must appear after all fixed arguments have been specified"
```

Some additional examples:

```
public void DoSomething(bool isEmployed, string personName, int personAge) { ... }

DoSomething(isEmployed:true, name, age); // currently CS1738, but would become legal
DoSomething(true, personName:name, age); // currently CS1738, but would become legal
DoSomething(name, isEmployed:true, age); // remains illegal
DoSomething(name, age, isEmployed:true); // remains illegal
DoSomething(true, personAge:age, personName:name); // already legal
```

This would also work with params:

```
public class Task
{
    public static Task When(TaskStatus all, TaskStatus any, params Task[] tasks);
}

Task.When(all: TaskStatus.RanToCompletion, any: TaskStatus.Faulted, task1, task2)
```

Detailed design

In §7.5.1 (Argument lists), the spec currently says:

An *argument* with an *argument-name* is referred to as a **named argument**, whereas an *argument* without an *argument-name* is a **positional argument**. It is an error for a positional argument to appear after a named argument in an *argument-list*.

The proposal is to remove this error and update the rules for finding the corresponding parameter for an argument (§7.5.1.1):

Arguments in the argument-list of instance constructors, methods, indexers and delegates:

- [existing rules]
- An unnamed argument corresponds to no parameter when it is after an out-of-position named argument or

a named params argument.

In particular, this prevents invoking `void M(bool a = true, bool b = true, bool c = true,);` with `M(c: false, valueB);`. The first argument is used out-of-position (the argument is used in first position, but the parameter named "c" is in third position), so the following arguments should be named.

In other words, non-trailing named arguments are only allowed when the name and the position result in finding the same corresponding parameter.

Drawbacks

This proposal exacerbates existing subtleties with named arguments in overload resolution. For instance:

```
void M(int x, int y) { }
void M<T>(T y, int x) { }

void M2()
{
    M(3, 4);
    M(y: 3, x: 4); // Invokes M(int, int)
    M(y: 3, 4); // Invokes M<T>(T, int)
}
```

You could get this situation today by swapping the parameters:

```
void M(int y, int x) { }
void M<T>(int x, T y) { }

void M2()
{
    M(3, 4);
    M(x: 3, y: 4); // Invokes M(int, int)
    M(3, y: 4); // Invokes M<T>(int, T)
}
```

Similarly, if you have two methods `void M(int a, int b)` and `void M(int x, string y)`, the mistaken invocation `M(x: 1, 2)` will produce a diagnostic based on the second overload ("cannot convert from 'int' to 'string'"). This problem already exists when the named argument is used in a trailing position.

Alternatives

There are a couple of alternatives to consider:

- The status quo
- Providing IDE assistance to fill-in all the names of trailing arguments when you type specific a name in the middle.

Both of those suffer from more verbosity, as they introduce multiple named arguments even if you just need one name of a literal at the beginning of the argument list.

Unresolved questions

Design meetings

The feature was briefly discussed in LDM on May 16th 2017, with approval in principle (ok to move to proposal/prototype). It was also briefly discussed on June 28th 2017.

Relates to initial discussion <https://github.com/dotnet/csharp-lang/issues/518> Relates to championed issue <https://github.com/dotnet/csharp-lang/issues/570>

private protected

12/28/2021 • 9 minutes to read • [Edit Online](#)

Summary

Expose the CLR `protectedAndInternal` accessibility level in C# as `private protected`.

Motivation

There are many circumstances in which an API contains members that are only intended to be implemented and used by subclasses contained in the assembly that provides the type. While the CLR provides an accessibility level for that purpose, it is not available in C#. Consequently API owners are forced to either use `internal` protection and self-discipline or a custom analyzer, or to use `protected` with additional documentation explaining that, while the member appears in the public documentation for the type, it is not intended to be part of the public API. For examples of the latter, see members of Roslyn's `CSharpCompilationOptions` whose names start with `Common`.

Directly providing support for this access level in C# enables these circumstances to be expressed naturally in the language.

Detailed design

`private protected` **access modifier**

We propose to add a new access modifier combination `private protected` (which can appear in any order among the modifiers). This maps to the CLR notion of `protectedAndInternal`, and borrows the same syntax currently used in C++/CLI.

A member declared `private protected` can be accessed within a subclass of its container if that subclass is in the same assembly as the member.

We modify the language specification as follows (additions in bold). Section numbers are not shown below as they may vary depending on which version of the specification it is integrated into.

The declared accessibility of a member can be one of the following:

- Public, which is selected by including a public modifier in the member declaration. The intuitive meaning of public is “access not limited”.
 - Protected, which is selected by including a protected modifier in the member declaration. The intuitive meaning of protected is “access limited to the containing class or types derived from the containing class”.
 - Internal, which is selected by including an internal modifier in the member declaration. The intuitive meaning of internal is “access limited to this assembly”.
 - Protected internal, which is selected by including both a protected and an internal modifier in the member declaration. The intuitive meaning of protected internal is “accessible within this assembly as well as types derived from the containing class”.
 - **Private protected, which is selected by including both a private and a protected modifier in the member declaration. The intuitive meaning of private protected is “accessible within this assembly by types derived from the containing class”.**
-

Depending on the context in which a member declaration takes place, only certain types of declared accessibility are permitted. Furthermore, when a member declaration does not include any access modifiers, the context in which the declaration takes place determines the default declared accessibility.

- Namespaces implicitly have public declared accessibility. No access modifiers are allowed on namespace declarations.
- Types declared directly in compilation units or namespaces (as opposed to within other types) can have public or internal declared accessibility and default to internal declared accessibility.
- Class members can have any of the five kinds of declared accessibility and default to private declared accessibility. [Note: A type declared as a member of a class can have any of the five kinds of declared accessibility, whereas a type declared as a member of a namespace can have only public or internal declared accessibility. end note]
- Struct members can have public, internal, or private declared accessibility and default to private declared accessibility because structs are implicitly sealed. Struct members introduced in a struct (that is, not inherited by that struct) cannot have protected*, * or protected internal**, or private protected** declared accessibility. [Note: A type declared as a member of a struct can have public, internal, or private declared accessibility, whereas a type declared as a member of a namespace can have only public or internal declared accessibility. end note]
- Interface members implicitly have public declared accessibility. No access modifiers are allowed on interface member declarations.
- Enumeration members implicitly have public declared accessibility. No access modifiers are allowed on enumeration member declarations.

The accessibility domain of a nested member M declared in a type T within a program P, is defined as follows (noting that M itself might possibly be a type):

- If the declared accessibility of M is public, the accessibility domain of M is the accessibility domain of T.
- If the declared accessibility of M is protected internal, let D be the union of the program text of P and the program text of any type derived from T, which is declared outside P. The accessibility domain of M is the intersection of the accessibility domain of T with D.
- **If the declared accessibility of M is private protected, let D be the intersection of the program text of P and the program text of any type derived from T. The accessibility domain of M is the intersection of the accessibility domain of T with D.**
- If the declared accessibility of M is protected, let D be the union of the program text of T and the program text of any type derived from T. The accessibility domain of M is the intersection of the accessibility domain of T with D.
- If the declared accessibility of M is internal, the accessibility domain of M is the intersection of the accessibility domain of T with the program text of P.
- If the declared accessibility of M is private, the accessibility domain of M is the program text of T.

When a protected or **private protected** instance member is accessed outside the program text of the class in which it is declared, and when a protected internal instance member is accessed outside the program text of the program in which it is declared, the access shall take place within a class declaration that derives from the class in which it is declared. Furthermore, the access is required to take place through an instance of that derived class type or a class type constructed from it. This restriction prevents one derived class from accessing protected members of other derived classes, even when the members are inherited from the same base class.

The permitted access modifiers and the default access for a type declaration depend on the context in which the declaration takes place (§9.5.2):

- Types declared in compilation units or namespaces can have public or internal access. The default is internal access.
- Types declared in classes can have public, protected internal, **private protected**, protected, internal, or private access. The default is private access.
- Types declared in structs can have public, internal, or private access. The default is private access.

A static class declaration is subject to the following restrictions:

- A static class shall not include a sealed or abstract modifier. (However, since a static class cannot be instantiated or derived from, it behaves as if it was both sealed and abstract.)
- A static class shall not include a class-base specification (§16.2.5) and cannot explicitly specify a base class or a list of implemented interfaces. A static class implicitly inherits from type object.
- A static class shall only contain static members (§16.4.8). [Note: All constants and nested types are classified as static members. end note]
- A static class shall not have members with protected**, private protected** or protected internal declared accessibility.

It is a compile-time error to violate any of these restrictions.

A class-member-declaration can have any one of the ~~five~~**six** possible kinds of declared accessibility (§9.5.2): public, **private protected**, protected internal, protected, internal, or private. Except for the protected internal **and private protected** combinations, it is a compile-time error to specify more than one access modifier. When a class-member-declaration does not include any access modifiers, private is assumed.

Non-nested types can have public or internal declared accessibility and have internal declared accessibility by default. Nested types can have these forms of declared accessibility too, plus one or more additional forms of declared accessibility, depending on whether the containing type is a class or struct:

- A nested type that is declared in a class can have any of ~~five~~**six** forms of declared accessibility (public, **private protected**, protected internal, protected, internal, or private) and, like other class members, defaults to private declared accessibility.
- A nested type that is declared in a struct can have any of three forms of declared accessibility (public, internal, or private) and, like other struct members, defaults to private declared accessibility.

The method overridden by an override declaration is known as the overridden base method For an override method M declared in a class C, the overridden base method is determined by examining each base class type of C, starting with the direct base class type of C and continuing with each successive direct base class type, until in a given base class type at least one accessible method is located which has the same signature as M after substitution of type arguments. For the purposes of locating the overridden base method, a method is considered accessible if it is public, if it is protected, if it is protected internal, or if it is **either internal or private protected** and declared in the same program as C.

The use of accessor-modifiers is governed by the following restrictions:

- An accessor-modifier shall not be used in an interface or in an explicit interface member implementation.
- For a property or indexer that has no override modifier, an accessor-modifier is permitted only if the property or indexer has both a get and set accessor, and then is permitted only on one of those accessors.
- For a property or indexer that includes an override modifier, an accessor shall match the accessor-modifier, if any, of the accessor being overridden.
- The accessor-modifier shall declare an accessibility that is strictly more restrictive than the declared accessibility of the property or indexer itself. To be precise:
 - If the property or indexer has a declared accessibility of public, the accessor-modifier may be either **private protected**, , protected internal, internal, protected, or private.
 - If the property or indexer has a declared accessibility of protected internal, the accessor-modifier may be either **private protected**, internal, protected, or private.
 - If the property or indexer has a declared accessibility of internal or protected, the accessor-modifier shall be either **private protected** or private.
 - If the property or indexer has a declared accessibility of **private protected**, the accessor-modifier shall be private.
 - If the property or indexer has a declared accessibility of private, no accessor-modifier may be used.

Since inheritance isn't supported for structs, the declared accessibility of a struct member cannot be protected, **private protected**, or protected internal.

Drawbacks

As with any language feature, we must question whether the additional complexity to the language is repaid in the additional clarity offered to the body of C# programs that would benefit from the feature.

Alternatives

An alternative would be the provision of an API combining an attribute and an analyzer. The attribute is placed by the programmer on an `internal` member to indicate that the member is intended to be used only in subclasses, and the analyzer checks that those restrictions are obeyed.

Unresolved questions

The implementation is largely complete. The only open work item is drafting a corresponding specification for VB.

Design meetings

TBD

Conditional ref expressions

12/28/2021 • 2 minutes to read • [Edit Online](#)

The pattern of binding a ref variable to one or another expression conditionally is not currently expressible in C#.

The typical workaround is to introduce a method like:

```
ref T Choice(bool condition, ref T consequence, ref T alternative)
{
    if (condition)
    {
        return ref consequence;
    }
    else
    {
        return ref alternative;
    }
}
```

Note that this is not an exact replacement of a ternary since all arguments must be evaluated at the call site.

The following will not work as expected:

```
// will crash with NRE because 'arr[0]' will be executed unconditionally
ref var r = ref Choice(arr != null, ref arr[0], ref otherArr[0]);
```

The proposed syntax would look like:

```
<condition> ? ref <consequence> : ref <alternative>;
```

The above attempt with "Choice" can be *correctly* written using ref ternary as:

```
ref var r = ref (arr != null ? ref arr[0]: ref otherArr[0]);
```

The difference from Choice is that consequence and alternative expressions are accessed in a *truly* conditional manner, so we do not see a crash if `arr == null`

The ternary ref is just a ternary where both alternative and consequence are refs. It will naturally require that consequence/alternative operands are LValues. It will also require that consequence and alternative have types that are identity convertible to each other.

The type of the expression will be computed similarly to the one for the regular ternary. I.E. in a case if consequence and alternative have identity convertible, but different types, the existing type-merging rules will apply.

Safe-to-return will be assumed conservatively from the conditional operands. If either is unsafe to return the whole thing is unsafe to return.

Ref ternary is an LValue and as such it can be passed/assigned/returned by reference;

```
// pass by reference
foo(ref (arr != null ? ref arr[0]: ref otherArr[0]));

// return by reference
return ref (arr != null ? ref arr[0]: ref otherArr[0]);
```

Being an LValue, it can also be assigned to.

```
// assign to
(arr != null ? ref arr[0]: ref otherArr[0]) = 1;
```

Ref ternary can be used in a regular (not ref) context as well. Although it would not be common since you could as well just use a regular ternary.

```
int x = (arr != null ? ref arr[0]: ref otherArr[0]);
```

Implementation notes:

The complexity of the implementation would seem to be the size of a moderate-to-large bug fix. - I.E not very expensive. I do not think we need any changes to the syntax or parsing. There is no effect on metadata or interop. The feature is completely expression based. No effect on debugging/PDB either

Allow digit separator after 0b or 0x

12/28/2021 • 2 minutes to read • [Edit Online](#)

In C# 7.2, we extend the set of places that digit separators (the underscore character) can appear in integral literals. [Beginning in C# 7.0, separators are permitted between the digits of a literal.](#) Now, in C# 7.2, we also permit digit separators before the first significant digit of a binary or hexadecimal literal, after the prefix.

```
123      // permitted in C# 1.0 and later
1_2_3    // permitted in C# 7.0 and later
0x1_2_3  // permitted in C# 7.0 and later
0b101    // binary literals added in C# 7.0
0b1_0_1  // permitted in C# 7.0 and later

// in C# 7.2, _ is permitted after the `0x` or `0b`
0x_1_2   // permitted in C# 7.2 and later
0b_1_0_1 // permitted in C# 7.2 and later
```

We do not permit a decimal integer literal to have a leading underscore. A token such as `_123` is an identifier.

Unmanaged type constraint

12/28/2021 • 4 minutes to read • [Edit Online](#)

Summary

The unmanaged constraint feature will give language enforcement to the class of types known as "unmanaged types" in the C# language spec. This is defined in section 18.2 as a type which is not a reference type and doesn't contain reference type fields at any level of nesting.

Motivation

The primary motivation is to make it easier to author low level interop code in C#. Unmanaged types are one of the core building blocks for interop code, yet the lack of support in generics makes it impossible to create re-usable routines across all unmanaged types. Instead developers are forced to author the same boiler plate code for every unmanaged type in their library:

```
int Hash(Point point) { ... }
int Hash(TimeSpan timeSpan) { ... }
```

To enable this type of scenario the language will be introducing a new constraint: unmanaged:

```
void Hash<T>(T value) where T : unmanaged
{
    ...
}
```

This constraint can only be met by types which fit into the unmanaged type definition in the C# language spec. Another way of looking at it is that a type satisfies the unmanaged constraint if it can also be used as a pointer.

```
Hash(new Point()); // Okay
Hash(42); // Okay
Hash("hello") // Error: Type string does not satisfy the unmanaged constraint
```

Type parameters with the unmanaged constraint can use all the features available to unmanaged types: pointers, fixed, etc ...

```
void Hash<T>(T value) where T : unmanaged
{
    // Okay
    fixed (T* p = &value)
    {
        ...
    }
}
```

This constraint will also make it possible to have efficient conversions between structured data and streams of bytes. This is an operation that is common in networking stacks and serialization layers:

```
Span<byte> Convert<T>(ref T value) where T : unmanaged
{
    ...
}
```

Such routines are advantageous because they are provably safe at compile time and allocation free. Interop authors today can not do this (even though it's at a layer where perf is critical). Instead they need to rely on allocating routines that have expensive runtime checks to verify values are correctly unmanaged.

Detailed design

The language will introduce a new constraint named `unmanaged`. In order to satisfy this constraint a type must be a struct and all the fields of the type must fall into one of the following categories:

- Have the type `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `long`, `ulong`, `char`, `float`, `double`, `decimal`, `bool`, `IntPtr` or `UIntPtr`.
- Be any `enum` type.
- Be a pointer type.
- Be a user defined struct that satisfies the `unmanaged` constraint.

Compiler generated instance fields, such as those backing auto-implemented properties, must also meet these constraints.

For example:

```
// Unmanaged type
struct Point
{
    int X;
    int Y {get; set;}
}

// Not an unmanaged type
struct Student
{
    string FirstName;
    string LastName;
}
```

The `unmanaged` constraint cannot be combined with `struct`, `class` or `new()`. This restriction derives from the fact that `unmanaged` implies `struct` hence the other constraints do not make sense.

The `unmanaged` constraint is not enforced by CLR, only by the language. To prevent mis-use by other languages, methods which have this constraint will be protected by a mod-req. This will prevent other languages from using type arguments which are not unmanaged types.

The token `unmanaged` in the constraint is not a keyword, nor a contextual keyword. Instead it is like `var` in that it is evaluated at that location and will either:

- Bind to user defined or referenced type named `unmanaged`: This will be treated just as any other named type constraint is treated.
- Bind to no type: This will be interpreted as the `unmanaged` constraint.

In the case there is a type named `unmanaged` and it is available without qualification in the current context, then there will be no way to use the `unmanaged` constraint. This parallels the rules surrounding the feature `var` and user defined types of the same name.

Drawbacks

The primary drawback of this feature is that it serves a small number of developers: typically low level library authors or frameworks. Hence it's spending precious language time for a small number of developers.

Yet these frameworks are often the basis for the majority of .NET applications out there. Hence performance / correctness wins at this level can have a ripple effect on the .NET ecosystem. This makes the feature worth considering even with the limited audience.

Alternatives

There are a couple of alternatives to consider:

- The status quo: The feature is not justified on its own merits and developers continue to use the implicit opt in behavior.

Questions

Metadata Representation

The F# language encodes the constraint in the signature file which means C# cannot re-use their representation. A new attribute will need to be chosen for this constraint. Additionally a method which has this constraint must be protected by a mod-req.

Blittable vs. Unmanaged

The F# language has a very [similar feature](#) which uses the keyword unmanaged. The blittable name comes from the use in Midori. May want to look to precedence here and use unmanaged instead.

Resolution The language decide to use unmanaged

Verifier

Does the verifier / runtime need to be updated to understand the use of pointers to generic type parameters? Or can it simply work as is without changes?

Resolution No changes needed. All pointer types are simply unverifiable.

Design meetings

n/a

Indexing `fixed` fields should not require pinning regardless of the movable/unmovable context.

12/28/2021 • 2 minutes to read • [Edit Online](#)

The change has the size of a bug fix. It can be in 7.3 and does not conflict with whatever direction we take further. This change is only about allowing the following scenario to work even though `s` is moveable. It is already valid when `s` is not moveable.

NOTE: in either case, it still requires `unsafe` context. It is possible to read uninitialized data or even out of range. That is not changing.

```
unsafe struct S
{
    public fixed int myFixedField[10];
}

class Program
{
    static S s;

    unsafe static void Main()
    {
        int p = s.myFixedField[5]; // indexing fixed-size array fields would be ok
    }
}
```

The main “challenge” that I see here is how to explain the relaxation in the spec. In particular, since the following would still need pinning. (because `s` is moveable and we explicitly use the field as a pointer)

```
unsafe struct S
{
    public fixed int myFixedField[10];
}

class Program
{
    static S s;

    unsafe static void Main()
    {
        int* ptr = s.myFixedField; // taking a pointer explicitly still requires pinning.
        int p = ptr[5];
    }
}
```

One reason why we require pinning of the target when it is movable is the artifact of our code generation strategy, - we always convert to an unmanaged pointer and thus force the user to pin via `fixed` statement. However, conversion to unmanaged is unnecessary when doing indexing. The same unsafe pointer math is equally applicable when we have the receiver in the form of a managed pointer. If we do that, then the intermediate ref is managed (GC-tracked) and the pinning is unnecessary.

The change <https://github.com/dotnet/roslyn/pull/24966> is a prototype PR that relaxes this requirement.

Pattern-based `fixed` statement

12/28/2021 • 3 minutes to read • [Edit Online](#)

Summary

Introduce a pattern that would allow types to participate in `fixed` statements.

Motivation

The language provides a mechanism for pinning managed data and obtain a native pointer to the underlying buffer.

```
fixed(byte* ptr = byteArray)
{
    // ptr is a native pointer to the first element of the array
    // byteArray is protected from being moved/collected by the GC for the duration of this block
}
```

The set of types that can participate in `fixed` is hardcoded and limited to arrays and `System.String`. Hardcoding "special" types does not scale when new primitives such as `ImmutableArray<T>`, `Span<T>`, `Utf8String` are introduced.

In addition, the current solution for `System.String` relies on a fairly rigid API. The shape of the API implies that `System.String` is a contiguous object that embeds UTF16 encoded data at a fixed offset from the object header. Such approach has been found problematic in several proposals that could require changes to the underlying layout. It would be desirable to be able to switch to something more flexible that decouples `System.String` object from its internal representation for the purpose of unmanaged interop.

Detailed design

Pattern

A viable pattern-based "fixed" need to:

- Provide the managed references to pin the instance and to initialize the pointer (preferably this is the same reference)
- Convey unambiguously the type of the unmanaged element (i.e. "char" for "string")
- Prescribe the behavior in "empty" case when there is nothing to refer to.
- Should not push API authors toward design decisions that hurt the use of the type outside of `fixed`.

I think the above could be satisfied by recognizing a specially named ref-returning member:

```
ref [readonly] T GetPinnableReference() .
```

In order to be used by the `fixed` statement the following conditions must be met:

1. There is only one such member provided for a type.
2. Returns by `ref` or `ref readonly`. (`readonly` is permitted so that authors of immutable/readonly types could implement the pattern without adding writeable API that could be used in safe code)
3. T is an unmanaged type. (since `T*` becomes the pointer type. The restriction will naturally expand if/when

the notion of "unmanaged" is expanded)

- Returns managed `nullptr` when there is no data to pin – probably the cheapest way to convey emptiness. (note that `""` string returns a ref to `'\0'` since strings are null-terminated)

Alternatively for the `#3` we can allow the result in empty cases be undefined or implementation-specific. That, however, may make the API more dangerous and prone to abuse and unintended compatibility burdens.

Translation

```
fixed(byte* ptr = thing)
{
    // <BODY>
}
```

becomes the following pseudocode (not all expressible in C#)

```
byte* ptr;
// specially decorated "pinned" IL local slot, not visible to user code.
pinned ref byte _pinned;

try
{
    // NOTE: null check is omitted for value types
    // NOTE: `thing` is evaluated only once (temporary is introduced if necessary)
    if (thing != null)
    {
        // obtain and "pin" the reference
        _pinned = ref thing.GetPinnableReference();

        // unsafe cast in IL
        ptr = (byte*)_pinned;
    }
    else
    {
        ptr = default(byte*);
    }

    // <BODY>
}
finally // finally can be omitted when not observable
{
    // "unpin" the object
    _pinned = nullptr;
}
```

Drawbacks

- GetPinnableReference is intended to be used only in `fixed`, but nothing prevents its use in safe code, so implementor must keep that in mind.

Alternatives

Users can introduce GetPinnableReference or similar member and use it as

```
fixed(byte* ptr = thing.GetPinnableReference())
{
    // <BODY>
}
```

There is no solution for `System.String` if alternative solution is desired.

Unresolved questions

- ☐ Behavior in "empty" state. - `nullptr` or `undefined` ?
- ☐ Should the extension methods be considered ?
- ☐ If a pattern is detected on `System.String`, should it win over ?

Design meetings

None yet.

Ref Local Reassignment

12/28/2021 • 2 minutes to read • [Edit Online](#)

In C# 7.3, we add support for rebinding the referent of a ref local variable or a ref parameter.

We add the following to the set of `assignment_operator`s.

```
assignment_operator
: '=' 'ref'
;
```

The `=ref` operator is called the **ref assignment operator**. It is not a *compound assignment operator*. The left operand must be an expression that binds to a ref local variable, a ref parameter (other than `this`), or an out parameter. The right operand must be an expression that yields an lvalue designating a value of the same type as the left operand.

The right operand must be definitely assigned at the point of the ref assignment.

When the left operand binds to an `out` parameter, it is an error if that `out` parameter has not been definitely assigned at the beginning of the ref assignment operator.

If the left operand is a writeable ref (i.e. it designates anything other than a `ref readonly` local or `in` parameter), then the right operand must be a writeable lvalue.

The ref assignment operator yields an lvalue of the assigned type. It is writeable if the left operand is writeable (i.e. not `ref readonly` or `in`).

The safety rules for this operator are:

- For a ref reassignment `e1 = ref e2`, the *ref-safe-to-escape* of `e2` must be at least as wide a scope as the *ref-safe-to-escape* of `e1`.

Where *ref-safe-to-escape* is defined in [Safety for ref-like types](#)

Stackalloc array initializers

12/28/2021 • 2 minutes to read • [Edit Online](#)

Summary

Allow array initializer syntax to be used with `stackalloc`.

Motivation

Ordinary arrays can have their elements initialized at creation time. It seems reasonable to allow that in `stackalloc` case.

The question of why such syntax is not allowed with `stackalloc` arises fairly frequently. See, for example, [#1112](#)

Detailed design

Ordinary arrays can be created through the following syntax:

```
new int[3]
new int[3] { 1, 2, 3 }
new int[] { 1, 2, 3 }
new[] { 1, 2, 3 }
```

We should allow stack allocated arrays be created through:

```
stackalloc int[3]    // currently allowed
stackalloc int[3] { 1, 2, 3 }
stackalloc int[] { 1, 2, 3 }
stackalloc[] { 1, 2, 3 }
```

The semantics of all cases is roughly the same as with arrays.

For example: in the last case the element type is inferred from the initializer and must be an "unmanaged" type.

NOTE: the feature is not dependent on the target being a `Span<T>`. It is just as applicable in `T*` case, so it does not seem reasonable to predicate it on `Span<T>` case.

Translation

The naive implementation could just initialize the array right after creation through a series of element-wise assignments.

Similarly to the case with arrays, it might be possible and desirable to detect cases where all or most of the elements are blittable types and use more efficient techniques by copying over the pre-created state of all the constant elements.

Drawbacks

Alternatives

This is a convenience feature. It is possible to just do nothing.

Unresolved questions

Design meetings

None yet.

Auto-Implemented Property Field-Targeted Attributes

12/28/2021 • 2 minutes to read • [Edit Online](#)

Summary

This feature intends to allow developers to apply attributes directly to the backing fields of auto-implemented properties.

Motivation

Currently it is not possible to apply attributes to the backing fields of auto-implemented properties. In those cases where the developer must use a field-targeting attribute they are forced to declare the field manually and use the more verbose property syntax. Given that C# has always supported field-targeted attributes on the generated backing field for events it makes sense to extend the same functionality to their property kin.

Detailed design

In short, the following would be legal C# and not produce a warning:

```
[Serializable]
public class Foo
{
    [field: NonSerialized]
    public string MySecret { get; set; }
}
```

This would result in the field-targeted attributes being applied to the compiler-generated backing field:

```
[Serializable]
public class Foo
{
    [NonSerialized]
    private string _mySecretBackingField;

    public string MySecret
    {
        get { return _mySecretBackingField; }
        set { _mySecretBackingField = value; }
    }
}
```

As mentioned, this brings parity with event syntax from C# 1.0 as the following is already legal and behaves as expected:

```
[Serializable]
public class Foo
{
    [field: NonSerialized]
    public event EventHandler MyEvent;
}
```

Drawbacks

There are two potential drawbacks to implementing this change:

1. Attempting to apply an attribute to the field of an auto-implemented property produces a compiler warning that the attributes in that block will be ignored. If the compiler were changed to support those attributes they would be applied to the backing field on a subsequent recompilation which could alter the behavior of the program at runtime.
2. The compiler does not currently validate the `AttributeUsage` targets of the attributes when attempting to apply them to the field of the auto-implemented property. If the compiler were changed to support field-targeted attributes and the attribute in question cannot be applied to a field the compiler would emit an error instead of a warning, breaking the build.

Expression variables in initializers

12/28/2021 • 2 minutes to read • [Edit Online](#)

Summary

We extend the features introduced in C# 7 to permit expressions containing expression variables (out variable declarations and declaration patterns) in field initializers, property initializers, ctor-initializers, and query clauses.

Motivation

This completes a couple of the rough edges left in the C# language due to lack of time.

Detailed design

We remove the restriction preventing the declaration of expression variables (out variable declarations and declaration patterns) in a ctor-initializer. Such a declared variable is in scope throughout the body of the constructor.

We remove the restriction preventing the declaration of expression variables (out variable declarations and declaration patterns) in a field or property initializer. Such a declared variable is in scope throughout the initializing expression.

We remove the restriction preventing the declaration of expression variables (out variable declarations and declaration patterns) in a query expression clause that is translated into the body of a lambda. Such a declared variable is in scope throughout that expression of the query clause.

Drawbacks

None.

Alternatives

The appropriate scope for expression variables declared in these contexts is not obvious, and deserves further LDM discussion.

Unresolved questions

- [] What is the appropriate scope for these variables?

Design meetings

None.

Support for == and != on tuple types

12/28/2021 • 4 minutes to read • [Edit Online](#)

Allow expressions `t1 == t2` where `t1` and `t2` are tuple or nullable tuple types of same cardinality, and evaluate them roughly as `temp1.Item1 == temp2.Item1 && temp1.Item2 == temp2.Item2` (assuming `var temp1 = t1; var temp2 = t2;`).

Conversely it would allow `t1 != t2` and evaluate it as

```
temp1.Item1 != temp2.Item1 || temp1.Item2 != temp2.Item2 .
```

In the nullable case, additional checks for `temp1.HasValue` and `temp2.HasValue` are used. For instance,

`nullableT1 == nullableT2` evaluates as

```
temp1.HasValue == temp2.HasValue ? (temp1.HasValue ? ... : true) : false .
```

When an element-wise comparison returns a non-bool result (for instance, when a non-bool user-defined `operator ==` or `operator !=` is used, or in a dynamic comparison), then that result will be either converted to `bool` or run through `operator true` or `operator false` to get a `bool`. The tuple comparison always ends up returning a `bool`.

As of C# 7.2, such code produces an error (

error CS0019: Operator '==' cannot be applied to operands of type '(...)' and '(...)'), unless there is a user-defined `operator==`.

Details

When binding the `==` (or `!=`) operator, the existing rules are: (1) dynamic case, (2) overload resolution, and (3) fail. This proposal adds a tuple case between (1) and (2): if both operands of a comparison operator are tuples (have tuple types or are tuple literals) and have matching cardinality, then the comparison is performed element-wise. This tuple equality is also lifted onto nullable tuples.

Both operands (and, in the case of tuple literals, their elements) are evaluated in order from left to right. Each pair of elements is then used as operands to bind the operator `==` (or `!=`), recursively. Any elements with compile-time type `dynamic` cause an error. The results of those element-wise comparisons are used as operands in a chain of conditional AND (or OR) operators.

For instance, in the context of `(int, (int, int)) t1, t2; , t1 == (1, (2, 3))` would evaluate as

```
temp1.Item1 == temp2.Item1 && temp1.Item2.Item1 == temp2.Item2.Item1 && temp1.Item2.Item2 == temp2.Item2.Item2
```

When a tuple literal is used as operand (on either side), it receives a converted tuple type formed by the element-wise conversions which are introduced when binding the operator `==` (or `!=`) element-wise.

For instance, in `(1L, 2, "hello") == (1, 2L, null)`, the converted type for both tuple literals is `(long, long, string)` and the second literal has no natural type.

Deconstruction and conversions to tuple

In `(a, b) == x`, the fact that `x` can deconstruct into two elements does not play a role. That could conceivably be in a future proposal, although it would raise questions about `x == y` (is this a simple comparison or an element-wise comparison, and if so using what cardinality?). Similarly, conversions to tuple play no role.

Tuple element names

When converting a tuple literal, we warn when an explicit tuple element name was provided in the literal, but it doesn't match the target tuple element name. We use the same rule in tuple comparison, so that assuming

```
(int a, int b) t we warn on d in t == (c, d: 0) .
```

Non-bool element-wise comparison results

If an element-wise comparison is dynamic in a tuple equality, we use a dynamic invocation of the operator `false` and negate that to get a `bool` and continue with further element-wise comparisons.

If an element-wise comparison returns some other non-bool type in a tuple equality, there are two cases:

- if the non-bool type converts to `bool`, we apply that conversion,
- if there is no such conversion, but the type has an operator `false`, we'll use that and negate the result.

In a tuple inequality, the same rules apply except that we'll use the operator `true` (without negation) instead of the operator `false`.

Those rules are similar to the rules involved for using a non-bool type in an `if` statement and some other existing contexts.

Evaluation order and special cases

The left-hand-side value is evaluated first, then the right-hand-side value, then the element-wise comparisons from left to right (including conversions, and with early exit based on existing rules for conditional AND/OR operators).

For instance, if there is a conversion from type `A` to type `B` and a method `(A, A) GetTuple()`, evaluating `(new A(1), (new B(2), new B(3))) == (new B(4), GetTuple())` means:

- `new A(1)`
- `new B(2)`
- `new B(3)`
- `new B(4)`
- `GetTuple()`
- then the element-wise conversions and comparisons and conditional logic is evaluated (convert `new A(1)` to type `B`, then compare it with `new B(4)`, and so on).

Comparing `null` to `null`

This is a special case from regular comparisons, that carries over to tuple comparisons. The `null == null` comparison is allowed, and the `null` literals do not get any type. In tuple equality, this means, `(0, null) == (0, null)` is also allowed and the `null` and tuple literals don't get a type either.

Comparing a nullable struct to `null` without `operator==`

This is another special case from regular comparisons, that carries over to tuple comparisons. If you have a `struct S` without `operator==`, the `(S?)x == null` comparison is allowed, and it is interpreted as `((S?).x).HasValue`. In tuple equality, the same rule is applied, so `(0, (S?)x) == (0, null)` is allowed.

Compatibility

If someone wrote their own `ValueTuple` types with an implementation of the comparison operator, it would have previously been picked up by overload resolution. But since the new tuple case comes before overload resolution, we would handle this case with tuple comparison instead of relying on the user-defined comparison.

Improved overload candidates

12/28/2021 • 2 minutes to read • [Edit Online](#)

Summary

The overload resolution rules have been updated in nearly every C# language update to improve the experience for programmers, making ambiguous invocations select the "obvious" choice. This has to be done carefully to preserve backward compatibility, but since we are usually resolving what would otherwise be error cases, these enhancements usually work out nicely.

1. When a method group contains both instance and static members, we discard the instance members if invoked without an instance receiver or context, and discard the static members if invoked with an instance receiver. When there is no receiver, we include only static members in a static context, otherwise both static and instance members. When the receiver is ambiguously an instance or type due to a color-color situation, we include both. A static context, where an implicit this instance receiver cannot be used, includes the body of members where no this is defined, such as static members, as well as places where this cannot be used, such as field initializers and constructor-initializers.
2. When a method group contains some generic methods whose type arguments do not satisfy their constraints, these members are removed from the candidate set.
3. For a method group conversion, candidate methods whose return type doesn't match up with the delegate's return type are removed from the set.

Nullable reference types in C#

12/28/2021 • 7 minutes to read • [Edit Online](#)

The goal of this feature is to:

- Allow developers to express whether a variable, parameter or result of a reference type is intended to be null or not.
- Provide warnings when such variables, parameters and results are not used according to that intent.

Expression of intent

The language already contains the `T?` syntax for value types. It is straightforward to extend this syntax to reference types.

It is assumed that the intent of an unadorned reference type `T` is for it to be non-null.

Checking of nullable references

A flow analysis tracks nullable reference variables. Where the analysis deems that they would not be null (e.g. after a check or an assignment), their value will be considered a non-null reference.

A nullable reference can also explicitly be treated as non-null with the postfix `x!` operator (the "damnit" operator), for when flow analysis cannot establish a non-null situation that the developer knows is there.

Otherwise, a warning is given if a nullable reference is dereferenced, or is converted to a non-null type.

A warning is given when converting from `S[]` to `T?[]` and from `S?[]` to `T[]`.

A warning is given when converting from `C<S>` to `C<T?>` except when the type parameter is covariant (`out`), and when converting from `C<S?>` to `C<T>` except when the type parameter is contravariant (`in`).

A warning is given on `C<T?>` if the type parameter has non-null constraints.

Checking of non-null references

A warning is given if a null literal is assigned to a non-null variable or passed as a non-null parameter.

A warning is also given if a constructor does not explicitly initialize non-null reference fields.

We cannot adequately track that all elements of an array of non-null references are initialized. However, we could issue a warning if no element of a newly created array is assigned to before the array is read from or passed on. That might handle the common case without being too noisy.

We need to decide whether `default(T)` generates a warning, or is simply treated as being of the type `T?`.

Metadata representation

Nullability adornments should be represented in metadata as attributes. This means that downlevel compilers will ignore them.

We need to decide if only nullable annotations are included, or there's also some indication of whether non-null was "on" in the assembly.

Generics

If a type parameter `T` has non-nullable constraints, it is treated as non-nullable within its scope.

If a type parameter is unconstrained or has only nullable constraints, the situation is a little more complex: this means that the corresponding type argument could be *either* nullable or non-nullable. The safe thing to do in that situation is to treat the type parameter as *both* nullable and non-nullable, giving warnings when either is violated.

It is worth considering whether explicit nullable reference constraints should be allowed. Note, however, that we cannot avoid having nullable reference types *implicitly* be constraints in certain cases (inherited constraints).

The `class` constraint is non-null. We can consider whether `class?` should be a valid nullable constraint denoting "nullable reference type".

Type inference

In type inference, if a contributing type is a nullable reference type, the resulting type should be nullable. In other words, nullness is propagated.

We should consider whether the `null` literal as a participating expression should contribute nullness. It doesn't today: for value types it leads to an error, whereas for reference types the null successfully converts to the plain type.

```
string? n = "world";
var x = b ? "Hello" : n; // string?
var y = b ? "Hello" : null; // string? or error
var z = b ? 7 : null; // Error today, could be int?
```

Null guard guidance

As a feature, nullable reference types allow developers to express their intent, and provide warnings through flow analysis if that intent is contradicted. There is a common question as to whether or not null guards are necessary.

Example of null guard

```
public void DoWork(Worker worker)
{
    // Guard against worker being null
    if (worker is null)
    {
        throw new ArgumentNullException(nameof(worker));
    }

    // Otherwise use worker argument
}
```

In the previous example, the `DoWork` function accepts a `Worker` and guards against it potentially being `null`. If the `worker` argument is `null`, the `DoWork` function will `throw`. With nullable reference types, the code in the previous example makes the intent that the `Worker` parameter would *not* be `null`. If the `DoWork` function was a public API, such as a NuGet package or a shared library - as guidance you should leave null guards in place. As a public API, the only guarantee that a caller isn't passing `null` is to guard against it.

Express intent

A more compelling use of the previous example is to express that the `Worker` parameter could be `null`, thus

making the null guard more appropriate. If you remove the null guard in the following example, the compiler warns that you may be dereferencing null. Regardless, both null guards are still valid.

```
public void DoWork(Worker? worker)
{
    // Guard against worker being null
    if (worker is null)
    {
        throw new ArgumentNullException(nameof(worker));
    }

    // Otherwise use worker argument
}
```

For non-public APIs, such as source code entirely in control by a developer or dev team - the nullable reference types could allow for the safe removal of null guards where the developers can guarantee it is not necessary. The feature can help with warnings, but it cannot guarantee that at runtime code execution could result in a `NullReferenceException`.

Breaking changes

Non-null warnings are an obvious breaking change on existing code, and should be accompanied with an opt-in mechanism.

Less obviously, warnings from nullable types (as described above) are a breaking change on existing code in certain scenarios where the nullability is implicit:

- Unconstrained type parameters will be treated as implicitly nullable, so assigning them to `object` or accessing e.g. `ToString` will yield warnings.
- if type inference infers nullness from `null` expressions, then existing code will sometimes yield nullable rather than non-nullable types, which can lead to new warnings.

So nullable warnings also need to be optional

Finally, adding annotations to an existing API will be a breaking change to users who have opted in to warnings, when they upgrade the library. This, too, merits the ability to opt in or out. "I want the bug fixes, but I am not ready to deal with their new annotations"

In summary, you need to be able to opt in/out of:

- Nullable warnings
- Non-null warnings
- Warnings from annotations in other files

The granularity of the opt-in suggests an analyzer-like model, where swaths of code can opt in and out with pragmas and severity levels can be chosen by the user. Additionally, per-library options ("ignore the annotations from JSON.NET until I'm ready to deal with the fall out") may be expressible in code as attributes.

The design of the opt-in/transition experience is crucial to the success and usefulness of this feature. We need to make sure that:

- Users can adopt nullability checking gradually as they want to
- Library authors can add nullability annotations without fear of breaking customers
- Despite these, there is not a sense of "configuration nightmare"

Tweaks

We could consider not using the `?` annotations on locals, but just observing whether they are used in accordance with what gets assigned to them. I don't favor this; I think we should uniformly let people express their intent.

We could consider a shorthand `T! x` on parameters, that auto-generates a runtime null check.

Certain patterns on generic types, such as `FirstOrDefault` or `TryGet`, have slightly weird behavior with non-nullable type arguments, because they explicitly yield default values in certain situations. We could try to nuance the type system to accommodate these better. For instance, we could allow `?` on unconstrained type parameters, even though the type argument could already be nullable. I doubt that it is worth it, and it leads to weirdness related to interaction with nullable *value* types.

Nullable value types

We could consider adopting some of the above semantics for nullable value types as well.

We already mentioned type inference, where we could infer `int?` from `(7, null)`, instead of just giving an error.

Another opportunity is to apply the flow analysis to nullable value types. When they are deemed non-null, we could actually allow using as the non-nullable type in certain ways (e.g. member access). We just have to be careful that the things that you can *already* do on a nullable value type will be preferred, for back compat reasons.

Recursive Pattern Matching

12/28/2021 • 12 minutes to read • [Edit Online](#)

Summary

Pattern matching extensions for C# enable many of the benefits of algebraic data types and pattern matching from functional languages, but in a way that smoothly integrates with the feel of the underlying language. Elements of this approach are inspired by related features in the programming languages [F#](#) and [Scala](#).

Detailed design

Is Expression

The `is` operator is extended to test an expression against a *pattern*.

```
relational_expression
    : is_pattern_expression
    ;
is_pattern_expression
    : relational_expression 'is' pattern
    ;
```

This form of *relational_expression* is in addition to the existing forms in the C# specification. It is a compile-time error if the *relational_expression* to the left of the `is` token does not designate a value or does not have a type.

Every *identifier* of the pattern introduces a new local variable that is *definitely assigned* after the `is` operator is `true` (i.e. *definitely assigned when true*).

Note: There is technically an ambiguity between *type* in an `is-expression` and *constant_pattern*, either of which might be a valid parse of a qualified identifier. We try to bind it as a type for compatibility with previous versions of the language; only if that fails do we resolve it as we do an expression in other contexts, to the first thing found (which must be either a constant or a type). This ambiguity is only present on the right-hand-side of an `is` expression.

Patterns

Patterns are used in the *is_pattern* operator, in a *switch_statement*, and in a *switch_expression* to express the shape of data against which incoming data (which we call the input value) is to be compared. Patterns may be recursive so that parts of the data may be matched against sub-patterns.

```

pattern
  : declaration_pattern
  | constant_pattern
  | var_pattern
  | positional_pattern
  | property_pattern
  | discard_pattern
  ;
declaration_pattern
  : type simple_designation
  ;
constant_pattern
  : constant_expression
  ;
var_pattern
  : 'var' designation
  ;
positional_pattern
  : type? '(' subpatterns? ')' property_subpattern? simple_designation?
  ;
subpatterns
  : subpattern
  | subpattern ',' subpatterns
  ;
subpattern
  : pattern
  | identifier ':' pattern
  ;
property_subpattern
  : '{' '}'
  | '{' subpatterns ',' '?' '}'
  ;
property_pattern
  : type? property_subpattern simple_designation?
  ;
simple_designation
  : single_variable_designation
  | discard_designation
  ;
discard_pattern
  : '_'
  ;

```

Declaration Pattern

```

declaration_pattern
  : type simple_designation
  ;

```

The *declaration_pattern* both tests that an expression is of a given type and casts it to that type if the test succeeds. This may introduce a local variable of the given type named by the given identifier, if the designation is a *single_variable_designation*. That local variable is *definitely assigned* when the result of the pattern-matching operation is `true`.

The runtime semantic of this expression is that it tests the runtime type of the left-hand *relational_expression* operand against the *type* in the pattern. If it is of that runtime type (or some subtype) and not `null`, the result of the `is operator` is `true`.

Certain combinations of static type of the left-hand-side and the given type are considered incompatible and result in compile-time error. A value of static type `E` is said to be *pattern-compatible* with a type `T` if there exists an identity conversion, an implicit reference conversion, a boxing conversion, an explicit reference conversion, or an unboxing conversion from `E` to `T`, or if one of those types is an open type. It is a compile-

time error if an input of type `E` is not *pattern-compatible* with the *type* in a type pattern that it is matched with.

The type pattern is useful for performing run-time type tests of reference types, and replaces the idiom

```
var v = expr as Type;
if (v != null) { // code using v
```

With the slightly more concise

```
if (expr is Type v) { // code using v
```

It is an error if *type* is a nullable value type.

The type pattern can be used to test values of nullable types: a value of type `Nullable<T>` (or a boxed `T`) matches a type pattern `T2 id` if the value is non-null and the type of `T2` is `T`, or some base type or interface of `T`. For example, in the code fragment

```
int? x = 3;
if (x is int v) { // code using v
```

The condition of the `if` statement is `true` at runtime and the variable `v` holds the value `3` of type `int` inside the block. After the block the variable `v` is in scope but not definitely assigned.

Constant Pattern

```
constant_pattern
    : constant_expression
    ;
```

A constant pattern tests the value of an expression against a constant value. The constant may be any constant expression, such as a literal, the name of a declared `const` variable, or an enumeration constant. When the input value is not an open type, the constant expression is implicitly converted to the type of the matched expression; if the type of the input value is not *pattern-compatible* with the type of the constant expression, the pattern-matching operation is an error.

The pattern `c` is considered matching the converted input value `e` if `object.Equals(c, e)` would return `true`.

We expect to see `e is null` as the most common way to test for `null` in newly written code, as it cannot invoke a user-defined `operator==`.

Var Pattern

```

var_pattern
: 'var' designation
;
designation
: simple_designation
| tuple_designation
;
simple_designation
: single_variable_designation
| discard_designation
;
single_variable_designation
: identifier
;
discard_designation
: _
;
tuple_designation
: '(' designations? ')'
;
designations
: designation
| designations ',' designation
;

```

If the *designation* is a *simple_designation*, an expression *e* matches the pattern. In other words, a match to a *var pattern* always succeeds with a *simple_designation*. If the *simple_designation* is a *single_variable_designation*, the value of *e* is bounds to a newly introduced local variable. The type of the local variable is the static type of *e*.

If the *designation* is a *tuple_designation*, then the pattern is equivalent to a *positional_pattern* of the form `(var designation, ...)` where the *designations* are those found within the *tuple_designation*. For example, the pattern `var (x, (y, z))` is equivalent to `(var x, (var y, var z))`.

It is an error if the name `var` binds to a type.

Discard Pattern

```

discard_pattern
: '_'
;

```

An expression *e* matches the pattern `_` always. In other words, every expression matches the discard pattern.

A discard pattern may not be used as the pattern of an *is_pattern_expression*.

Positional Pattern

A positional pattern checks that the input value is not `null`, invokes an appropriate `Deconstruct` method, and performs further pattern matching on the resulting values. It also supports a tuple-like pattern syntax (without the type being provided) when the type of the input value is the same as the type containing `Deconstruct`, or if the type of the input value is a tuple type, or if the type of the input value is `object` or `ITuple` and the runtime type of the expression implements `ITuple`.

```

positional_pattern
  : type? '(' subpatterns? ')' property_subpattern? simple_designation?
  ;
subpatterns
  : subpattern
  | subpattern ',' subpatterns
  ;
subpattern
  : pattern
  | identifier ':' pattern
  ;

```

If the *type* is omitted, we take it to be the static type of the input value.

Given a match of an input value to the pattern *type* `(subpattern_list)`, a method is selected by searching in *type* for accessible declarations of `Deconstruct` and selecting one among them using the same rules as for the deconstruction declaration.

It is an error if a *positional_pattern* omits the type, has a single *subpattern* without an *identifier*, has no *property_subpattern* and has no *simple_designation*. This disambiguates between a *constant_pattern* that is parenthesized and a *positional_pattern*.

In order to extract the values to match against the patterns in the list,

- If *type* was omitted and the input value's type is a tuple type, then the number of subpatterns is required to be the same as the cardinality of the tuple. Each tuple element is matched against the corresponding *subpattern*, and the match succeeds if all of these succeed. If any *subpattern* has an *identifier*, then that must name a tuple element at the corresponding position in the tuple type.
- Otherwise, if a suitable `Deconstruct` exists as a member of *type*, it is a compile-time error if the type of the input value is not *pattern-compatible* with *type*. At runtime the input value is tested against *type*. If this fails then the positional pattern match fails. If it succeeds, the input value is converted to this type and `Deconstruct` is invoked with fresh compiler-generated variables to receive the `out` parameters. Each value that was received is matched against the corresponding *subpattern*, and the match succeeds if all of these succeed. If any *subpattern* has an *identifier*, then that must name a parameter at the corresponding position of `Deconstruct`.
- Otherwise if *type* was omitted, and the input value is of type `object` or `ITuple` or some type that can be converted to `ITuple` by an implicit reference conversion, and no *identifier* appears among the subpatterns, then we match using `ITuple`.
- Otherwise the pattern is a compile-time error.

The order in which subpatterns are matched at runtime is unspecified, and a failed match may not attempt to match all subpatterns.

Example

This example uses many of the features described in this specification

```

var newState = (GetState(), action, hasKey) switch {
    (DoorState.Closed, Action.Open, _) => DoorState.Opened,
    (DoorState.Opened, Action.Close, _) => DoorState.Closed,
    (DoorState.Closed, Action.Lock, true) => DoorState.Locked,
    (DoorState.Locked, Action.Unlock, true) => DoorState.Closed,
    (var state, _, _) => state };

```

Property Pattern

A property pattern checks that the input value is not `null` and recursively matches values extracted by the use of accessible properties or fields.

```

property_pattern
    : type? property_subpattern simple_designation?
    ;
property_subpattern
    : '{' '}'
    | '{' subpatterns ','? '}'
    ;

```

It is an error if any *subpattern* of a *property_pattern* does not contain an *identifier* (it must be of the second form, which has an *identifier*). A trailing comma after the last subpattern is optional.

Note that a null-checking pattern falls out of a trivial property pattern. To check if the string `s` is non-null, you can write any of the following forms

```

if (s is object o) ... // o is of type object
if (s is string x) ... // x is of type string
if (s is {} x) ... // x is of type string
if (s is {}) ...

```

Given a match of an expression *e* to the pattern `type { property_pattern_list }`, it is a compile-time error if the expression *e* is not *pattern-compatible* with the type *T* designated by *type*. If the type is absent, we take it to be the static type of *e*. If the *identifier* is present, it declares a pattern variable of type *type*. Each of the identifiers appearing on the left-hand-side of its *property_pattern_list* must designate an accessible readable property or field of *T*. If the *simple_designation* of the *property_pattern* is present, it defines a pattern variable of type *T*.

At runtime, the expression is tested against *T*. If this fails then the property pattern match fails and the result is `false`. If it succeeds, then each *property_subpattern* field or property is read and its value matched against its corresponding pattern. The result of the whole match is `false` only if the result of any of these is `false`. The order in which subpatterns are matched is not specified, and a failed match may not match all subpatterns at runtime. If the match succeeds and the *simple_designation* of the *property_pattern* is a *single_variable_designation*, it defines a variable of type *T* that is assigned the matched value.

Note: The property pattern can be used to pattern-match with anonymous types.

Example

```

if (o is string { Length: 5 } s)

```

Switch Expression

A *switch_expression* is added to support `switch`-like semantics for an expression context.

The C# language syntax is augmented with the following syntactic productions:

```

multiplicative_expression
: switch_expression
| multiplicative_expression '*' switch_expression
| multiplicative_expression '/' switch_expression
| multiplicative_expression '%' switch_expression
;
switch_expression
: range_expression 'switch' '{' '}'
| range_expression 'switch' '{' switch_expression_arms ',' '}'
;
switch_expression_arms
: switch_expression_arm
| switch_expression_arms ',' switch_expression_arm
;
switch_expression_arm
: pattern case_guard? '=>' expression
;
case_guard
: 'when' null_coalescing_expression
;

```

The *switch_expression* is not permitted as an *expression_statement*.

We are looking at relaxing this in a future revision.

The type of the *switch_expression* is the *best common type* of the expressions appearing to the right of the `=>` tokens of the *switch_expression_arms* if such a type exists and the expression in every arm of the switch expression can be implicitly converted to that type. In addition, we add a new *switch_expression_conversion*, which is a predefined implicit conversion from a switch expression to every type `T` for which there exists an implicit conversion from each arm's expression to `T`.

It is an error if some *switch_expression_arm*'s pattern cannot affect the result because some previous pattern and guard will always match.

A switch expression is said to be *exhaustive* if some arm of the switch expression handles every value of its input. The compiler shall produce a warning if a switch expression is not *exhaustive*.

At runtime, the result of the *switch_expression* is the value of the *expression* of the first *switch_expression_arm* for which the expression on the left-hand-side of the *switch_expression* matches the *switch_expression_arm*'s pattern, and for which the *case_guard* of the *switch_expression_arm*, if present, evaluates to `true`. If there is no such *switch_expression_arm*, the *switch_expression* throws an instance of the exception

`System.Runtime.CompilerServices.SwitchExpressionException`.

Optional parens when switching on a tuple literal

In order to switch on a tuple literal using the *switch_statement*, you have to write what appear to be redundant parens

```

switch ((a, b))
{

```

To permit

```

switch (a, b)
{

```

the parentheses of the switch statement are optional when the expression being switched on is a tuple literal.

Order of evaluation in pattern-matching

Giving the compiler flexibility in reordering the operations executed during pattern-matching can permit flexibility that can be used to improve the efficiency of pattern-matching. The (unenforced) requirement would be that properties accessed in a pattern, and the Deconstruct methods, are required to be "pure" (side-effect free, idempotent, etc). That doesn't mean that we would add purity as a language concept, only that we would allow the compiler flexibility in reordering operations.

Resolution 2018-04-04 LDM: confirmed: the compiler is permitted to reorder calls to `Deconstruct`, property accesses, and invocations of methods in `ITuple`, and may assume that returned values are the same from multiple calls. The compiler should not invoke functions that cannot affect the result, and we will be very careful before making any changes to the compiler-generated order of evaluation in the future.

Some Possible Optimizations

The compilation of pattern matching can take advantage of common parts of patterns. For example, if the top-level type test of two successive patterns in a *switch_statement* is the same type, the generated code can skip the type test for the second pattern.

When some of the patterns are integers or strings, the compiler can generate the same kind of code it generates for a switch-statement in earlier versions of the language.

For more on these kinds of optimizations, see [\[Scott and Ramsey \(2000\)\]](#).

default interface methods

12/28/2021 • 27 minutes to read • [Edit Online](#)

Summary

Add support for *virtual extension methods* - methods in interfaces with concrete implementations. A class or struct that implements such an interface is required to have a single *most specific* implementation for the interface method, either implemented by the class or struct, or inherited from its base classes or interfaces. Virtual extension methods enable an API author to add methods to an interface in future versions without breaking source or binary compatibility with existing implementations of that interface.

These are similar to Java's ["Default Methods"](#).

(Based on the likely implementation technique) this feature requires corresponding support in the CLI/CLR. Programs that take advantage of this feature cannot run on earlier versions of the platform.

Motivation

The principal motivations for this feature are

- Default interface methods enable an API author to add methods to an interface in future versions without breaking source or binary compatibility with existing implementations of that interface.
- The feature enables C# to interoperate with APIs targeting [Android \(Java\)](#) and [iOS \(Swift\)](#), which support similar features.
- As it turns out, adding default interface implementations provides the elements of the "traits" language feature ([https://en.wikipedia.org/wiki/Trait_\(computer_programming\)](https://en.wikipedia.org/wiki/Trait_(computer_programming))). Traits have proven to be a powerful programming technique (<http://scg.unibe.ch/archive/papers/Scha03aTraits.pdf>).

Detailed design

The syntax for an interface is extended to permit

- member declarations that declare constants, operators, static constructors, and nested types;
- a *body* for a method or indexer, property, or event accessor (that is, a "default" implementation);
- member declarations that declare static fields, methods, properties, indexers, and events;
- member declarations using the explicit interface implementation syntax; and
- Explicit access modifiers (the default access is `public`).

Members with bodies permit the interface to provide a "default" implementation for the method in classes and structs that do not provide an overriding implementation.

Interfaces may not contain instance state. While static fields are now permitted, instance fields are not permitted in interfaces. Instance auto-properties are not supported in interfaces, as they would implicitly declare a hidden field.

Static and private methods permit useful refactoring and organization of code used to implement the interface's public API.

A method override in an interface must use the explicit interface implementation syntax.

It is an error to declare a class type, struct type, or enum type within the scope of a type parameter that was declared with a *variance annotation*. For example, the declaration of `C` below is an error.

```
interface IOuter<out T>
{
    class C { } // error: class declaration within the scope of variant type parameter 'T'
}
```

Concrete methods in interfaces

The simplest form of this feature is the ability to declare a *concrete method* in an interface, which is a method with a body.

```
interface IA
{
    void M() { WriteLine("IA.M"); }
}
```

A class that implements this interface need not implement its concrete method.

```
class C : IA { } // OK

IA i = new C();
i.M(); // prints "IA.M"
```

The final override for `IA.M` in class `C` is the concrete method `M` declared in `IA`. Note that a class does not inherit members from its interfaces; that is not changed by this feature:

```
new C().M(); // error: class 'C' does not contain a member 'M'
```

Within an instance member of an interface, `this` has the type of the enclosing interface.

Modifiers in interfaces

The syntax for an interface is relaxed to permit modifiers on its members. The following are permitted: `private`, `protected`, `internal`, `public`, `virtual`, `abstract`, `sealed`, `static`, `extern`, and `partial`.

TODO: check what other modifiers exist.

An interface member whose declaration includes a body is a `virtual` member unless the `sealed` or `private` modifier is used. The `virtual` modifier may be used on a function member that would otherwise be implicitly `virtual`. Similarly, although `abstract` is the default on interface members without bodies, that modifier may be given explicitly. A non-virtual member may be declared using the `sealed` keyword.

It is an error for a `private` or `sealed` function member of an interface to have no body. A `private` function member may not have the modifier `sealed`.

Access modifiers may be used on interface members of all kinds of members that are permitted. The access level `public` is the default but it may be given explicitly.

Open Issue: We need to specify the precise meaning of the access modifiers such as `protected` and `internal`, and which declarations do and do not override them (in a derived interface) or implement them (in a class that implements the interface).

Interfaces may declare `static` members, including nested types, methods, indexers, properties, events, and static constructors. The default access level for all interface members is `public`.

Interfaces may not declare instance constructors, destructors, or fields.

Closed Issue: Should operator declarations be permitted in an interface? Probably not conversion operators, but what about others? **Decision:** Operators are permitted *except* for conversion, equality, and inequality operators.

Closed Issue: Should `new` be permitted on interface member declarations that hide members from base interfaces? **Decision:** Yes.

Closed Issue: We do not currently permit `partial` on an interface or its members. That would require a separate proposal. **Decision:** Yes. <https://github.com/dotnet/csharplang/blob/master/meetings/2018/LDM-2018-10-17.md#permit-partial-in-interface>

Overrides in interfaces

Override declarations (i.e. those containing the `override` modifier) allow the programmer to provide a most specific implementation of a virtual member in an interface where the compiler or runtime would not otherwise find one. It also allows turning an abstract member from a super-interface into a default member in a derived interface. An override declaration is permitted to *explicitly* override a particular base interface method by qualifying the declaration with the interface name (no access modifier is permitted in this case). Implicit overrides are not permitted.

```
interface IA
{
    void M() { WriteLine("IA.M"); }
}
interface IB : IA
{
    override void IA.M() { WriteLine("IB.M"); } // explicitly named
}
interface IC : IA
{
    override void M() { WriteLine("IC.M"); } // implicitly named
}
```

Override declarations in interfaces may not be declared `sealed`.

Public `virtual` function members in an interface may be overridden in a derived interface explicitly (by qualifying the name in the override declaration with the interface type that originally declared the method, and omitting an access modifier).

`virtual` function members in an interface may only be overridden explicitly (not implicitly) in derived interfaces, and members that are not `public` may only be implemented in a class or struct explicitly (not implicitly). In either case, the overridden or implemented member must be *accessible* where it is overridden.

Reabstraction

A virtual (concrete) method declared in an interface may be overridden to be abstract in a derived interface

```
interface IA
{
    void M() { WriteLine("IA.M"); }
}
interface IB : IA
{
    abstract void IA.M();
}
class C : IB { } // error: class 'C' does not implement 'IA.M'.
```

The `abstract` modifier is not required in the declaration of `IB.M` (that is the default in interfaces), but it is probably good practice to be explicit in an override declaration.

This is useful in derived interfaces where the default implementation of a method is inappropriate and a more appropriate implementation should be provided by implementing classes.

Open Issue: Should reabstraction be permitted?

The most specific override rule

We require that every interface and class have a *most specific override* for every virtual member among the overrides appearing in the type or its direct and indirect interfaces. The *most specific override* is a unique override that is more specific than every other override. If there is no override, the member itself is considered the most specific override.

One override `M1` is considered *more specific* than another override `M2` if `M1` is declared on type `T1`, `M2` is declared on type `T2`, and either

1. `T1` contains `T2` among its direct or indirect interfaces, or
2. `T2` is an interface type but `T1` is not an interface type.

For example:

```
interface IA
{
    void M() { WriteLine("IA.M"); }
}
interface IB : IA
{
    void IA.M() { WriteLine("IB.M"); }
}
interface IC : IA
{
    void IA.M() { WriteLine("IC.M"); }
}
interface ID : IB, IC { } // error: no most specific override for 'IA.M'
abstract class C : IB, IC { } // error: no most specific override for 'IA.M'
abstract class D : IA, IB, IC // ok
{
    public abstract void M();
}
```

The most specific override rule ensures that a conflict (i.e. an ambiguity arising from diamond inheritance) is resolved explicitly by the programmer at the point where the conflict arises.

Because we support explicit abstract overrides in interfaces, we could do so in classes as well

```
abstract class E : IA, IB, IC // ok
{
    abstract void IA.M();
}
```

Open issue: should we support explicit interface abstract overrides in classes?

In addition, it is an error if in a class declaration the most specific override of some interface method is an abstract override that was declared in an interface. This is an existing rule restated using the new terminology.

```
interface IF
{
    void M();
}
abstract class F : IF { } // error: 'F' does not implement 'IF.M'
```

It is possible for a virtual property declared in an interface to have a most specific override for its `get` accessor in one interface and a most specific override for its `set` accessor in a different interface. This is considered a violation of the *most specific override* rule.

`static` and `private` methods

Because interfaces may now contain executable code, it is useful to abstract common code into private and static methods. We now permit these in interfaces.

Closed issue: Should we support private methods? Should we support static methods? **Decision: YES**

Open issue: should we permit interface methods to be `protected` or `internal` or other access? If so, what are the semantics? Are they `virtual` by default? If so, is there a way to make them non-virtual?

Open issue: If we support static methods, should we support (static) operators?

Base interface invocations

Code in a type that derives from an interface with a default method can explicitly invoke that interface's "base" implementation.

```
interface I0
{
    void M() { Console.WriteLine("I0"); }
}
interface I1 : I0
{
    override void M() { Console.WriteLine("I1"); }
}
interface I2 : I0
{
    override void M() { Console.WriteLine("I2"); }
}
interface I3 : I1, I2
{
    // an explicit override that invoke's a base interface's default method
    void I0.M() { I2.base.M(); }
}
```

An instance (nonstatic) method is permitted to invoke the implementation of an accessible instance method in a direct base interface nonvirtually by naming it using the syntax `base(Type).M`. This is useful when an override that is required to be provided due to diamond inheritance is resolved by delegating to one particular base implementation.

```

interface IA
{
    void M() { WriteLine("IA.M"); }
}
interface IB : IA
{
    override void IA.M() { WriteLine("IB.M"); }
}
interface IC : IA
{
    override void IA.M() { WriteLine("IC.M"); }
}

class D : IA, IB, IC
{
    void IA.M() { base(IB).M(); }
}

```

When a `virtual` or `abstract` member is accessed using the syntax `base(Type).M`, it is required that `Type` contains a unique *most specific override* for `M`.

Binding base clauses

Interfaces now contain types. These types may be used in the base clause as base interfaces. When binding a base clause, we may need to know the set of base interfaces to bind those types (e.g. to lookup in them and to resolve protected access). The meaning of an interface's base clause is thus circularly defined. To break the cycle, we add a new language rules corresponding to a similar rule already in place for classes.

While determining the meaning of the *interface_base* of an interface, the base interfaces are temporarily assumed to be empty. Intuitively this ensures that the meaning of a base clause cannot recursively depend on itself.

We used to have the following rules:

"When a class B derives from a class A, it is a compile-time error for A to depend on B. A class **directly depends on** its direct base class (if any) and **directly depends on** the ~~class~~ within which it is immediately nested (if any). Given this definition, the complete set of ~~classes~~ upon which a class depends is the reflexive and transitive closure of the **directly depends on** relationship."

It is a compile-time error for an interface to directly or indirectly inherit from itself. The **base interfaces** of an interface are the explicit base interfaces and their base interfaces. In other words, the set of base interfaces is the complete transitive closure of the explicit base interfaces, their explicit base interfaces, and so on.

We are adjusting them as follows:

When a class B derives from a class A, it is a compile-time error for A to depend on B. A class **directly depends on** its direct base class (if any) and **directly depends on** the *type* within which it is immediately nested (if any).

When an interface IB extends an interface IA, it is a compile-time error for IA to depend on IB. An interface **directly depends on** its direct base interfaces (if any) and **directly depends on** the type within which it is immediately nested (if any).

Given these definitions, the complete set of **types** upon which a type depends is the reflexive and transitive closure of the **directly depends on** relationship.

Effect on existing programs

The rules presented here are intended to have no effect on the meaning of existing programs.

Example 1:

```

interface IA
{
    void M();
}
class C: IA // Error: IA.M has no concrete most specific override in C
{
    public static void M() { } // method unrelated to 'IA.M' because static
}

```

Example 2:

```

interface IA
{
    void M();
}
class Base: IA
{
    void IA.M() { }
}
class Derived: Base, IA // OK, all interface members have a concrete most specific override
{
    private void M() { } // method unrelated to 'IA.M' because private
}

```

The same rules give similar results to the analogous situation involving default interface methods:

```

interface IA
{
    void M() { }
}
class Derived: IA // OK, all interface members have a concrete most specific override
{
    private void M() { } // method unrelated to 'IA.M' because private
}

```

Closed issue: confirm that this is an intended consequence of the specification. **Decision: YES**

Runtime method resolution

Closed Issue: The spec should describe the runtime method resolution algorithm in the face of interface default methods. We need to ensure that the semantics are consistent with the language semantics, e.g. which declared methods do and do not override or implement an `internal` method.

CLR support API

In order for compilers to detect when they are compiling for a runtime that supports this feature, libraries for such runtimes are modified to advertise that fact through the API discussed in

<https://github.com/dotnet/corefx/issues/17116>. We add

```

namespace System.Runtime.CompilerServices
{
    public static class RuntimeFeature
    {
        // Presence of the field indicates runtime support
        public const string DefaultInterfaceImplementation = nameof(DefaultInterfaceImplementation);
    }
}

```

Open issue: Is that the best name for the *CLR* feature? The CLR feature does much more than just that (e.g. relaxes protection constraints, supports overrides in interfaces, etc). Perhaps it should be called something like "concrete methods in interfaces", or "traits"?

Further areas to be specified

- [] It would be useful to catalog the kinds of source and binary compatibility effects caused by adding default interface methods and overrides to existing interfaces.

Drawbacks

This proposal requires a coordinated update to the CLR specification (to support concrete methods in interfaces and method resolution). It is therefore fairly "expensive" and it may be worth doing in combination with other features that we also anticipate would require CLR changes.

Alternatives

None.

Unresolved questions

- Open questions are called out throughout the proposal, above.
- See also <https://github.com/dotnet/csharplang/issues/406> for a list of open questions.
- The detailed specification must describe the resolution mechanism used at runtime to select the precise method to be invoked.
- The interaction of metadata produced by new compilers and consumed by older compilers needs to be worked out in detail. For example, we need to ensure that the metadata representation that we use does not cause the addition of a default implementation in an interface to break an existing class that implements that interface when compiled by an older compiler. This may affect the metadata representation that we can use.
- The design must consider interoperability with other languages and existing compilers for other languages.

Resolved Questions

Abstract Override

The earlier draft spec contained the ability to "reabstract" an inherited method:

```
interface IA
{
    void M();
}
interface IB : IA
{
    override void M() { }
}
interface IC : IB
{
    override void M(); // make it abstract again
}
```

My notes for 2017-03-20 showed that we decided not to allow this. However, there are at least two use cases for it:

1. The Java APIs, with which some users of this feature hope to interoperate, depend on this facility.
2. Programming with *traits* benefits from this. Reabstraction is one of the elements of the "traits" language feature ([https://en.wikipedia.org/wiki/Trait_\(computer_programming\)](https://en.wikipedia.org/wiki/Trait_(computer_programming))). The following is permitted with

classes:

```
public abstract class Base
{
    public abstract void M();
}
public abstract class A : Base
{
    public override void M() { }
}
public abstract class B : A
{
    public override abstract void M(); // reabstract Base.M
}
```

Unfortunately this code cannot be refactored as a set of interfaces (traits) unless this is permitted. By the *Jared principle of greed*, it should be permitted.

Closed issue: Should reabstraction be permitted? [YES] My notes were wrong. The [LDM notes](#) say that reabstraction is permitted in an interface. Not in a class.

Virtual Modifier vs Sealed Modifier

From [Aleksey Tsingauz](#):

We decided to allow modifiers explicitly stated on interface members, unless there is a reason to disallow some of them. This brings an interesting question around virtual modifier. Should it be required on members with default implementation?

We could say that:

- if there is no implementation and neither virtual, nor sealed are specified, we assume the member is abstract.
- if there is an implementation and neither abstract, nor sealed are specified, we assume the member is virtual.
- sealed modifier is required to make a method neither virtual, nor abstract.

Alternatively, we could say that virtual modifier is required for a virtual member. I.e, if there is a member with implementation not explicitly marked with virtual modifier, it is neither virtual, nor abstract. This approach might provide better experience when a method is moved from a class to an interface:

- an abstract method stays abstract.
- a virtual method stays virtual.
- a method without any modifier stays neither virtual, nor abstract.
- sealed modifier cannot be applied to a method that is not an override.

What do you think?

Closed Issue: Should a concrete method (with implementation) be implicitly `virtual`? [YES]

Decisions: Made in the LDM 2017-04-05:

1. non-virtual should be explicitly expressed through `sealed` or `private`.
2. `sealed` is the keyword to make interface instance members with bodies non-virtual
3. We want to allow all modifiers in interfaces
4. Default accessibility for interface members is public, including nested types

- private function members in interfaces are implicitly sealed, and `sealed` is not permitted on them.
- Private classes (in interfaces) are permitted and can be sealed, and that means sealed in the class sense of sealed.
- Absent a good proposal, partial is still not allowed on interfaces or their members.

Binary Compatibility 1

When a library provides a default implementation

```
interface I1
{
    void M() { Impl1 }
}
interface I2 : I1
{
}
class C : I2
{
}
```

We understand that the implementation of `I1.M` in `C` is `I1.M`. What if the assembly containing `I2` is changed as follows and recompiled

```
interface I2 : I1
{
    override void M() { Impl2 }
}
```

but `C` is not recompiled. What happens when the program is run? An invocation of `(C as I1).M()`

- Runs `I1.M`
- Runs `I2.M`
- Throws some kind of runtime error

Decision: Made 2017-04-11: Runs `I2.M`, which is the unambiguously most specific override at runtime.

Event accessors (closed)

Closed Issue: Can an event be overridden "piecewise"?

Consider this case:

```
public interface I1
{
    event T e1;
}
public interface I2 : I1
{
    override event T
    {
        add { }
        // error: "remove" accessor missing
    }
}
```

This "partial" implementation of the event is not permitted because, as in a class, the syntax for an event declaration does not permit only one accessor; both (or neither) must be provided. You could accomplish the same thing by permitting the abstract remove accessor in the syntax to be implicitly abstract by the absence of a

body:

```
public interface I1
{
    event T e1;
}
public interface I2 : I1
{
    override event T
    {
        add { }
        remove; // implicitly abstract
    }
}
```

Note that *this is a new (proposed) syntax*. In the current grammar, event accessors have a mandatory body.

Closed Issue: Can an event accessor be (implicitly) abstract by the omission of a body, similarly to the way that methods in interfaces and property accessors are (implicitly) abstract by the omission of a body?

Decision: (2017-04-18) No, event declarations require both concrete accessors (or neither).

Reabstraction in a Class (closed)

Closed Issue: We should confirm that this is permitted (otherwise adding a default implementation would be a breaking change):

```
interface I1
{
    void M() { }
}
abstract class C : I1
{
    public abstract void M(); // implement I1.M with an abstract method in C
}
```

Decision: (2017-04-18) Yes, adding a body to an interface member declaration shouldn't break C.

Sealed Override (closed)

The previous question implicitly assumes that the `sealed` modifier can be applied to an `override` in an interface. This contradicts the draft specification. Do we want to permit sealing an override? Source and binary compatibility effects of sealing should be considered.

Closed Issue: Should we permit sealing an override?

Decision: (2017-04-18) Let's not allow `sealed` on overrides in interfaces. The only use of `sealed` on interface members is to make them non-virtual in their initial declaration.

Diamond inheritance and classes (closed)

The draft of the proposal prefers class overrides to interface overrides in diamond inheritance scenarios:

We require that every interface and class have a *most specific override* for every interface method among the overrides appearing in the type or its direct and indirect interfaces. The *most specific override* is a unique override that is more specific than every other override. If there is no override, the method itself is considered the most specific override.

One override `M1` is considered *more specific* than another override `M2` if `M1` is declared on type `T1`, `M2` is declared on type `T2`, and either

1. `T1` contains `T2` among its direct or indirect interfaces, or
2. `T2` is an interface type but `T1` is not an interface type.

The scenario is this

```
interface IA
{
    void M();
}
interface IB : IA
{
    override void M() { WriteLine("IB"); }
}
class Base : IA
{
    void IA.M() { WriteLine("Base"); }
}
class Derived : Base, IB // allowed?
{
    static void Main()
    {
        Ia a = new Derived();
        a.M();           // what does it do?
    }
}
```

We should confirm this behavior (or decide otherwise)

Closed Issue: Confirm the draft spec, above, for *most specific override* as it applies to mixed classes and interfaces (a class takes priority over an interface). See <https://github.com/dotnet/csharplang/blob/master/meetings/2017/LDM-2017-04-19.md#diamonds-with-classes>.

Interface methods vs structs (closed)

There are some unfortunate interactions between default interface methods and structs.

```
interface IA
{
    public void M() { }
}
struct S : IA
{
}
```

Note that interface members are not inherited:

```
var s = default(S);
s.M(); // error: 'S' does not contain a member 'M'
```

Consequently, the client must box the struct to invoke interface methods

```
IA s = default(S); // an S, boxed
s.M(); // ok
```

Boxing in this way defeats the principal benefits of a `struct` type. Moreover, any mutation methods will have no apparent effect, because they are operating on a *boxed copy* of the struct:

```

interface IB
{
    public void Increment() { P += 1; }
    public int P { get; set; }
}
struct T : IB
{
    public int P { get; set; } // auto-property
}

T t = default(T);
Console.WriteLine(t.P); // prints 0
(t as IB).Increment();
Console.WriteLine(t.P); // prints 0

```

Closed Issue: What can we do about this:

1. Forbid a `struct` from inheriting a default implementation. All interface methods would be treated as abstract in a `struct`. Then we may take time later to decide how to make it work better.
2. Come up with some kind of code generation strategy that avoids boxing. Inside a method like `IB.Increment`, the type of `this` would perhaps be akin to a type parameter constrained to `IB`. In conjunction with that, to avoid boxing in the caller, non-abstract methods would be inherited from interfaces. This may increase compiler and CLR implementation work substantially.
3. Not worry about it and just leave it as a wart.
4. Other ideas?

Decision: Not worry about it and just leave it as a wart. See

<https://github.com/dotnet/csharpplang/blob/master/meetings/2017/LDM-2017-04-19.md#structs-and-default-implementations>.

Base interface invocations (closed)

The draft spec suggests a syntax for base interface invocations inspired by Java: `Interface.base.M()`. We need to select a syntax, at least for the initial prototype. My favorite is `base<Interface>.M()`.

Closed Issue: What is the syntax for a base member invocation?

Decision: The syntax is `base(Interface).M()`. See

<https://github.com/dotnet/csharpplang/blob/master/meetings/2017/LDM-2017-04-19.md#base-invocation>. The interface so named must be a base interface, but does not need to be a direct base interface.

Open Issue: Should base interface invocations be permitted in class members?

Decision: Yes. <https://github.com/dotnet/csharpplang/blob/master/meetings/2017/LDM-2017-04-19.md#base-invocation>

Overriding non-public interface members (closed)

In an interface, non-public members from base interfaces are overridden using the `override` modifier. If it is an "explicit" override that names the interface containing the member, the access modifier is omitted.

Closed Issue: If it is an "implicit" override that does not name the interface, does the access modifier have to match?

Decision: Only public members may be implicitly overridden, and the access must match. See

<https://github.com/dotnet/csharpplang/blob/master/meetings/2017/LDM-2017-04-18.md#dim-implementing->

[a-non-public-interface-member-not-in-list.](#)

Open Issue: Is the access modifier required, optional, or omitted on an explicit override such as

```
override void IB.M() {} ?
```

Open Issue: Is `override` required, optional, or omitted on an explicit override such as `void IB.M() {}` ?

How does one implement a non-public interface member in a class? Perhaps it must be done explicitly?

```
interface IA
{
    internal void MI();
    protected void MP();
}
class C : IA
{
    // are these implementations?
    internal void MI() {}
    protected void MP() {}
}
```

Closed Issue: How does one implement a non-public interface member in a class?

Decision: You can only implement non-public interface members explicitly. See

<https://github.com/dotnet/csharplang/blob/master/meetings/2017/LDM-2017-04-18.md#dim-implementing-a-non-public-interface-member-not-in-list>.

Decision: No `override` keyword permitted on interface members.

<https://github.com/dotnet/csharplang/blob/master/meetings/2018/LDM-2018-10-17.md#does-an-override-in-an-interface-introduce-a-new-member>

Binary Compatibility 2 (closed)

Consider the following code in which each type is in a separate assembly

```
interface I1
{
    void M() { Impl1 }
}
interface I2 : I1
{
    override void M() { Impl2 }
}
interface I3 : I1
{
}
class C : I2, I3
{
}
```

We understand that the implementation of `I1.M` in `C` is `I2.M`. What if the assembly containing `I3` is changed as follows and recompiled

```
interface I3 : I1
{
    override void M() { Impl3 }
}
```

but `c` is not recompiled. What happens when the program is run? An invocation of `(C as I1).M()`

1. Runs `I1.M`
2. Runs `I2.M`
3. Runs `I3.M`
4. Either 2 or 3, deterministically
5. Throws some kind of runtime exception

Decision: Throw an exception (5). See

<https://github.com/dotnet/csharplang/blob/master/meetings/2018/LDM-2018-10-17.md#issues-in-default-interface-methods>.

Permit `partial` in interface? (closed)

Given that interfaces may be used in ways analogous to the way abstract classes are used, it may be useful to declare them `partial`. This would be particularly useful in the face of generators.

Proposal: Remove the language restriction that interfaces and members of interfaces may not be declared `partial`.

Decision: Yes. See <https://github.com/dotnet/csharplang/blob/master/meetings/2018/LDM-2018-10-17.md#permit-partial-in-interface>.

Main in an interface? (closed)

Open Issue: Is a `static Main` method in an interface a candidate to be the program's entry point?

Decision: Yes. See <https://github.com/dotnet/csharplang/blob/master/meetings/2018/LDM-2018-10-17.md#main-in-an-interface>.

Confirm intent to support public non-virtual methods (closed)

Can we please confirm (or reverse) our decision to permit non-virtual public methods in an interface?

```
interface IA
{
    public sealed void M() { }
}
```

Semi-Closed Issue: (2017-04-18) We think it is going to be useful, but will come back to it. This is a mental model tripping block.

Decision: Yes. <https://github.com/dotnet/csharplang/blob/master/meetings/2018/LDM-2018-10-17.md#confirm-that-we-support-public-non-virtual-methods>.

Does an `override` in an interface introduce a new member? (closed)

There are a few ways to observe whether an override declaration introduces a new member or not.

```

interface IA
{
    void M(int x) { }
}
interface IB : IA
{
    override void M(int y) { }
}
interface IC : IB
{
    static void M2()
    {
        M(y: 3); // permitted?
    }
    override void IB.M(int z) { } // permitted? What does it override?
}

```

Open Issue: Does an override declaration in an interface introduce a new member? (closed)

In a class, an overriding method is "visible" in some senses. For example, the names of its parameters take precedence over the names of parameters in the overridden method. It may be possible to duplicate that behavior in interfaces, as there is always a most specific override. But do we want to duplicate that behavior?

Also, it is possible to "override" an override method? [Moot]

Decision: No `override` keyword permitted on interface members.

<https://github.com/dotnet/csharpplang/blob/master/meetings/2018/LDM-2018-10-17.md#does-an-override-in-an-interface-introduce-a-new-member>.

Properties with a private accessor (closed)

We say that private members are not virtual, and the combination of virtual and private is disallowed. But what about a property with a private accessor?

```

interface IA
{
    public virtual int P
    {
        get => 3;
        private set => { }
    }
}

```

Is this allowed? Is the `set` accessor here `virtual` or not? Can it be overridden where it is accessible? Does the following implicitly implement only the `get` accessor?

```

class C : IA
{
    public int P
    {
        get => 4;
        set { }
    }
}

```

Is the following presumably an error because `IA.P.set` isn't virtual and also because it isn't accessible?

```

class C : IA
{
    int IA.P
    {
        get => 4;
        set { }
    }
}

```

Decision: The first example looks valid, while the last does not. This is resolved analogously to how it already works in C#. <https://github.com/dotnet/csharplang/blob/master/meetings/2018/LDM-2018-10-17.md#properties-with-a-private-accessor>

Base Interface Invocations, round 2 (closed)

Our previous "resolution" to how to handle base invocations doesn't actually provide sufficient expressiveness. It turns out that in C# and the CLR, unlike Java, you need to specify both the interface containing the method declaration and the location of the implementation you want to invoke.

I propose the following syntax for base calls in interfaces. I'm not in love with it, but it illustrates what any syntax must be able to express:

```

interface I1 { void M(); }
interface I2 { void M(); }
interface I3 : I1, I2 { void I1.M() { } void I2.M() { } }
interface I4 : I1, I2 { void I1.M() { } void I2.M() { } }
interface I5 : I3, I4
{
    void I1.M()
    {
        base<I3>(I1).M(); // calls I3's implementation of I1.M
        base<I4>(I1).M(); // calls I4's implementation of I1.M
    }
    void I2.M()
    {
        base<I3>(I2).M(); // calls I3's implementation of I2.M
        base<I4>(I2).M(); // calls I4's implementation of I2.M
    }
}

```

If there is no ambiguity, you can write it more simply

```

interface I1 { void M(); }
interface I3 : I1 { void I1.M() { } }
interface I4 : I1 { void I1.M() { } }
interface I5 : I3, I4
{
    void I1.M()
    {
        base<I3>.M(); // calls I3's implementation of I1.M
        base<I4>.M(); // calls I4's implementation of I1.M
    }
}

```

Or

```

interface I1 { void M(); }
interface I2 { void M(); }
interface I3 : I1, I2 { void I1.M() { } void I2.M() { } }
interface I5 : I3
{
    void I1.M()
    {
        base(I1).M(); // calls I3's implementation of I1.M
    }
    void I2.M()
    {
        base(I2).M(); // calls I3's implementation of I2.M
    }
}

```

Or

```

interface I1 { void M(); }
interface I3 : I1 { void I1.M() { } }
interface I5 : I3
{
    void I1.M()
    {
        base.M(); // calls I3's implementation of I1.M
    }
}

```

Decision: Decided on `base(N.I1<T>).M(s)`, conceding that if we have an invocation binding there may be problem here later on. <https://github.com/dotnet/csharpplang/blob/master/meetings/2018/LDM-2018-11-14.md#default-interface-implementations>

Warning for struct not implementing default method? (closed)

@vancem asserts that we should seriously consider producing a warning if a value type declaration fails to override some interface method, even if it would inherit an implementation of that method from an interface. Because it causes boxing and undermines constrained calls.

Decision: This seems like something more suited for an analyzer. It also seems like this warning could be noisy, since it would fire even if the default interface method is never called and no boxing will ever occur. <https://github.com/dotnet/csharpplang/blob/master/meetings/2018/LDM-2018-10-17.md#warning-for-struct-not-implementing-default-method>

Interface static constructors (closed)

When are interface static constructors run? The current CLI draft proposes that it occurs when the first static method or field is accessed. If there are neither of those then it might never be run??

[2018-10-09 The CLR team proposes "Going to mirror what we do for valuetypes (cctor check on access to each instance method)"]

Decision: Static constructors are also run on entry to instance methods, if the static constructor was not `beforefieldinit`, in which case static constructors are run before access to the first static field.

<https://github.com/dotnet/csharpplang/blob/master/meetings/2018/LDM-2018-10-17.md#when-are-interface-static-constructors-run>

Async Streams

12/28/2021 • 20 minutes to read • [Edit Online](#)

Summary

C# has support for iterator methods and async methods, but no support for a method that is both an iterator and an async method. We should rectify this by allowing for `await` to be used in a new form of `async` iterator, one that returns an `IAsyncEnumerable<T>` or `IAsyncEnumerator<T>` rather than an `IEnumerable<T>` or `IEnumerator<T>`, with `IAsyncEnumerable<T>` consumable in a new `await foreach`. An `IAsyncDisposable` interface is also used to enable asynchronous cleanup.

Detailed design

Interfaces

IAsyncDisposable

There has been much discussion of `IAsyncDisposable` (e.g. <https://github.com/dotnet/roslyn/issues/114>) and whether it's a good idea. However, it's a required concept to add in support of async iterators. Since `finally` blocks may contain `await`s, and since `finally` blocks need to be run as part of disposing of iterators, we need async disposal. It's also just generally useful any time cleaning up of resources might take any period of time, e.g. closing files (requiring flushes), deregistering callbacks and providing a way to know when deregistration has completed, etc.

The following interface is added to the core .NET libraries (e.g. System.Private.CoreLib / System.Runtime):

```
namespace System
{
    public interface IAsyncDisposable
    {
        ValueTask DisposeAsync();
    }
}
```

As with `Dispose`, invoking `DisposeAsync` multiple times is acceptable, and subsequent invocations after the first should be treated as nops, returning a synchronously completed successful task (`DisposeAsync` need not be thread-safe, though, and need not support concurrent invocation). Further, types may implement both `IDisposable` and `IAsyncDisposable`, and if they do, it's similarly acceptable to invoke `Dispose` and then `DisposeAsync` or vice versa, but only the first should be meaningful and subsequent invocations of either should be a nop. As such, if a type does implement both, consumers are encouraged to call once and only once the more relevant method based on the context, `Dispose` in synchronous contexts and `DisposeAsync` in asynchronous ones.

(I'm leaving discussion of how `IAsyncDisposable` interacts with `using` to a separate discussion. And coverage of how it interacts with `foreach` is handled later in this proposal.)

Alternatives considered:

- `DisposeAsync` *accepting a* `CancellationToken`: while in theory it makes sense that anything async can be canceled, disposal is about cleanup, closing things out, free'ing resources, etc., which is generally not something that should be canceled; cleanup is still important for work that's canceled. The same `CancellationToken` that caused the actual work to be canceled would typically be the same token passed to `DisposeAsync`, making `DisposeAsync` worthless because cancellation of the work would cause `DisposeAsync` to be a nop. If someone wants to avoid being blocked waiting for disposal, they can avoid waiting on the resulting `ValueTask`, or wait on it only for some period of time.
- `DisposeAsync` *returning a* `Task`: Now that a non-generic `ValueTask` exists and can be constructed from an `IValueTaskSource`, returning `ValueTask` from `DisposeAsync` allows an existing object to be reused as the promise representing the eventual async completion of `DisposeAsync`, saving a `Task` allocation in the case where `DisposeAsync` completes asynchronously.
- *Configuring* `DisposeAsync` *with a* `bool continueOnCapturedContext` (`ConfigureAwait`): While there may be issues related to how such a concept is exposed to `using`, `foreach`, and other language constructs that consume this, from an interface perspective it's not actually doing any `await` 'ing and there's nothing to configure... consumers of the `ValueTask` can consume it however they wish.
- `IAsyncDisposable` *inheriting* `IDisposable`: Since only one or the other should be used, it doesn't make sense to force types to implement both.
- `IDisposableAsync` *instead of* `IAsyncDisposable`: We've been following the naming that things/types are an "async something" whereas operations are "done async", so types have "Async" as a prefix and methods have "Async" as a suffix.

IAsyncEnumerable / IAsyncEnumerator

Two interfaces are added to the core .NET libraries:

```
namespace System.Collections.Generic
{
    public interface IAsyncEnumerable<out T>
    {
        IAsyncEnumerator<T> GetAsyncEnumerator(CancellationToken cancellationToken = default);
    }

    public interface IAsyncEnumerator<out T> : IAsyncDisposable
    {
        ValueTask<bool> MoveNextAsync();
        T Current { get; }
    }
}
```

Typical consumption (without additional language features) would look like:

```
IAsyncEnumerator<T> enumerator = enumerable.GetAsyncEnumerator();
try
{
    while (await enumerator.MoveNextAsync())
    {
        Use(enumerator.Current);
    }
}
finally { await enumerator.DisposeAsync(); }
```

Discarded options considered:

- `Task<bool> MoveNextAsync(); T current { get; }`: Using `Task<bool>` would support using a cached task object to represent synchronous, successful `MoveNextAsync` calls, but an allocation would still be required for

asynchronous completion. By returning `ValueTask<bool>`, we enable the enumerator object to itself implement `IValueTaskSource<bool>` and be used as the backing for the `ValueTask<bool>` returned from `MoveNextAsync`, which in turn allows for significantly reduced overheads.

- `ValueTask<(bool, T)> MoveNextAsync();` : It's not only harder to consume, but it means that `T` can no longer be covariant.
- `ValueTask<T?> TryMoveNextAsync();` : Not covariant.
- `Task<T?> TryMoveNextAsync();` : Not covariant, allocations on every call, etc.
- `ITask<T?> TryMoveNextAsync();` : Not covariant, allocations on every call, etc.
- `ITask<(bool, T)> TryMoveNextAsync();` : Not covariant, allocations on every call, etc.
- `Task<bool> TryMoveNextAsync(out T result);` : The `out` result would need to be set when the operation returns synchronously, not when it asynchronously completes the task potentially sometime long in the future, at which point there'd be no way to communicate the result.
- `IEnumerator<T>` *not implementing* `IDisposable` : We could choose to separate these. However, doing so complicates certain other areas of the proposal, as code must then be able to deal with the possibility that an enumerator doesn't provide disposal, which makes it difficult to write pattern-based helpers. Further, it will be common for enumerators to have a need for disposal (e.g. any C# async iterator that has a finally block, most things enumerating data from a network connection, etc.), and if one doesn't, it is simple to implement the method purely as `public ValueTask DisposeAsync() => default(ValueTask);` with minimal additional overhead.
- `IEnumerator<T> GetAsyncEnumerator();` : No cancellation token parameter.

Viable alternative:

```
namespace System.Collections.Generic
{
    public interface IAsyncEnumerable<out T>
    {
        IEnumerator<T> GetAsyncEnumerator();
    }

    public interface IAsyncEnumerator<out T> : IDisposable
    {
        ValueTask<bool> WaitForNextAsync();
        T TryGetNext(out bool success);
    }
}
```

`TryGetNext` is used in an inner loop to consume items with a single interface call as long as they're available synchronously. When the next item can't be retrieved synchronously, it returns false, and any time it returns false, a caller must subsequently invoke `WaitForNextAsync` to either wait for the next item to be available or to determine that there will never be another item. Typical consumption (without additional language features) would look like:

```

IEnumerator<T> enumerator = enumerable.GetAsyncEnumerator();
try
{
    while (await enumerator.WaitForNextAsync())
    {
        while (true)
        {
            int item = enumerator.TryGetNext(out bool success);
            if (!success) break;
            Use(item);
        }
    }
}
finally { await enumerator.DisposeAsync(); }

```

The advantage of this is two-fold, one minor and one major:

- *Minor: Allows for an enumerator to support multiple consumers.* There may be scenarios where it's valuable for an enumerator to support multiple concurrent consumers. That can't be achieved when `MoveNextAsync` and `Current` are separate such that an implementation can't make their usage atomic. In contrast, this approach provides a single method `TryGetNext` that supports pushing the enumerator forward and getting the next item, so the enumerator can enable atomicity if desired. However, it's likely that such scenarios could also be enabled by giving each consumer its own enumerator from a shared enumerable. Further, we don't want to enforce that every enumerator support concurrent usage, as that would add non-trivial overheads to the majority case that doesn't require it, which means a consumer of the interface generally couldn't rely on this any way.
- *Major: Performance.* The `MoveNextAsync` / `Current` approach requires two interface calls per operation, whereas the best case for `WaitForNextAsync` / `TryGetNext` is that most iterations complete synchronously, enabling a tight inner loop with `TryGetNext`, such that we only have one interface call per operation. This can have a measurable impact in situations where the interface calls dominate the computation.

However, there are non-trivial downsides, including significantly increased complexity when consuming these manually, and an increased chance of introducing bugs when using them. And while the performance benefits show up in microbenchmarks, we don't believe they'll be impactful in the vast majority of real usage. If it turns out they are, we can introduce a second set of interfaces in a light-up fashion.

Discarded options considered:

- `ValueTask<bool> WaitForNextAsync(); bool TryGetNext(out T result);` : `out` parameters can't be covariant. There's also a small impact here (an issue with the try pattern in general) that this likely incurs a runtime write barrier for reference type results.

Cancellation

There are several possible approaches to supporting cancellation:

1. `IAsyncEnumerable<T>` / `IAsyncEnumerator<T>` are cancellation-agnostic: `CancellationToken` doesn't appear anywhere. Cancellation is achieved by logically baking the `CancellationToken` into the enumerable and/or enumerator in whatever manner is appropriate, e.g. when calling an iterator, passing the `CancellationToken` as an argument to the iterator method and using it in the body of the iterator, as is done with any other parameter.
2. `IAsyncEnumerator<T>.GetAsyncEnumerator(CancellationToken)` : You pass a `CancellationToken` to `GetAsyncEnumerator`, and subsequent `MoveNextAsync` operations respect it however it can.
3. `IAsyncEnumerator<T>.MoveNextAsync(CancellationToken)` : You pass a `CancellationToken` to each individual `MoveNextAsync` call.
4. 1 && 2: You both embed `CancellationToken`s into your enumerable/enumerator and pass `CancellationToken`s into `GetAsyncEnumerator`.

5. 1 && 3: You both embed `CancellationToken`s into your enumerable/enumerator and pass `CancellationToken`s into `MoveNextAsync`.

From a purely theoretical perspective, (5) is the most robust, in that (a) `MoveNextAsync` accepting a `CancellationToken` enables the most fine-grained control over what's canceled, and (b) `CancellationToken` is just any other type that can be passed as an argument into iterators, embedded in arbitrary types, etc.

However, there are multiple problems with that approach:

- How does a `CancellationToken` passed to `GetAsyncEnumerator` make it into the body of the iterator? We could expose a new `iterator` keyword that you could dot off of to get access to the `CancellationToken` passed to `GetEnumerator`, but a) that's a lot of additional machinery, b) we're making it a very first-class citizen, and c) the 99% case would seem to be the same code both calling an iterator and calling `GetAsyncEnumerator` on it, in which case it can just pass the `CancellationToken` as an argument into the method.
- How does a `CancellationToken` passed to `MoveNextAsync` get into the body of the method? This is even worse, as if it's exposed off of an `iterator` local object, its value could change across awaits, which means any code that registered with the token would need to unregister from it prior to awaits and then re-register after; it's also potentially quite expensive to need to do such registering and unregistering in every `MoveNextAsync` call, regardless of whether implemented by the compiler in an iterator or by a developer manually.
- How does a developer cancel a `foreach` loop? If it's done by giving a `CancellationToken` to an enumerable/enumerator, then either a) we need to support `foreach` 'ing over enumerators, which raises them to being first-class citizens, and now you need to start thinking about an ecosystem built up around enumerators (e.g. LINQ methods) or b) we need to embed the `CancellationToken` in the enumerable anyway by having some `WithCancellation` extension method off of `IAsyncEnumerable<T>` that would store the provided token and then pass it into the wrapped enumerable's `GetAsyncEnumerator` when the `GetAsyncEnumerator` on the returned struct is invoked (ignoring that token). Or, you can just use the `CancellationToken` you have in the body of the `foreach`.
- If/when query comprehensions are supported, how would the `CancellationToken` supplied to `GetEnumerator` or `MoveNextAsync` be passed into each clause? The easiest way would simply be for the clause to capture it, at which point whatever token is passed to `GetAsyncEnumerator` / `MoveNextAsync` is ignored.

An earlier version of this document recommended (1), but we since switched to (4).

The two main problems with (1):

- producers of cancellable enumerables have to implement some boilerplate, and can only leverage the compiler's support for async-iterators to implement a `IAsyncEnumerable<T> GetAsyncEnumerator(CancellationToken)` method.
- it is likely that many producers would be tempted to just add a `CancellationToken` parameter to their async-enumerable signature instead, which will prevent consumers from passing the cancellation token they want when they are given an `IAsyncEnumerable` type.

There are two main consumption scenarios:

1. `await foreach (var i in GetData(token)) ...` where the consumer calls the async-iterator method,
2. `await foreach (var i in givenIAsyncEnumerable.WithCancellation(token)) ...` where the consumer deals with a given `IAsyncEnumerable` instance.

We find that a reasonable compromise to support both scenarios in a way that is convenient for both producers and consumers of async-streams is to use a specially annotated parameter in the async-iterator method. The `[EnumeratorCancellation]` attribute is used for this purpose. Placing this attribute on a parameter tells the compiler that if a token is passed to the `GetAsyncEnumerator` method, that token should be used instead of the

value originally passed for the parameter.

Consider `IAsyncEnumerable<int> GetData([EnumeratorCancellation] CancellationToken token = default)`. The implementer of this method can simply use the parameter in the method body. The consumer can use either consumption patterns above:

1. if you use `GetData(token)`, then the token is saved into the async-enumerable and will be used in iteration,
2. if you use `givenIAsyncEnumerable.WithCancellation(token)`, then the token passed to `GetAsyncEnumerator` will supersede any token saved in the async-enumerable.

foreach

`foreach` will be augmented to support `IAsyncEnumerable<T>` in addition to its existing support for `IEnumerable<T>`. And it will support the equivalent of `IAsyncEnumerable<T>` as a pattern if the relevant members are exposed publicly, falling back to using the interface directly if not, in order to enable struct-based extensions that avoid allocating as well as using alternative awaitables as the return type of `MoveNextAsync` and `DisposeAsync`.

Syntax

Using the syntax:

```
foreach (var i in enumerable)
```

C# will continue to treat `enumerable` as a synchronous enumerable, such that even if it exposes the relevant APIs for async enumerables (exposing the pattern or implementing the interface), it will only consider the synchronous APIs.

To force `foreach` to instead only consider the asynchronous APIs, `await` is inserted as follows:

```
await foreach (var i in enumerable)
```

No syntax would be provided that would support using either the async or the sync APIs; the developer must choose based on the syntax used.

Discarded options considered:

- `foreach (var i in await enumerable)`: This is already valid syntax, and changing its meaning would be a breaking change. This means to `await` the `enumerable`, get back something synchronously iterable from it, and then synchronously iterate through that.
- `foreach (var i await in enumerable)`, `foreach (var await i in enumerable)`, `foreach (await var i in enumerable)`: These all suggest that we're awaiting the next item, but there are other awaits involved in `foreach`, in particular if the enumerable is an `IAsyncDisposable`, we will be `await`'ing its async disposal. That `await` is as the scope of the `foreach` rather than for each individual element, and thus the `await` keyword deserves to be at the `foreach` level. Further, having it associated with the `foreach` gives us a way to describe the `foreach` with a different term, e.g. a "await foreach". But more importantly, there's value in considering `foreach` syntax at the same time as `using` syntax, so that they remain consistent with each other, and `using (await ...)` is already valid syntax.
- `foreach await (var i in enumerable)`

Still to consider:

- `foreach` today does not support iterating through an enumerator. We expect it will be more common to have `IAsyncEnumerator<T>`'s handed around, and thus it's tempting to support `await foreach` with both

`IEnumerable<T>` and `IAsyncEnumerator<T>`. But once we add such support, it introduces the question of whether `IAsyncEnumerator<T>` is a first-class citizen, and whether we need to have overloads of combinators that operate on enumerators in addition to enumerables? Do we want to encourage methods to return enumerators rather than enumerables? We should continue to discuss this. If we decide we don't want to support it, we might want to introduce an extension method

`public static IEnumerable<T> AsEnumerable<T>(this IAsyncEnumerator<T> enumerator);` that would allow an enumerator to still be `foreach`'d. If we decide we do want to support it, we'll need to also decide on whether the `await foreach` would be responsible for calling `DisposeAsync` on the enumerator, and the answer is likely "no, control over disposal should be handled by whoever called `GetEnumerator`."

Pattern-based Compilation

The compiler will bind to the pattern-based APIs if they exist, preferring those over using the interface (the pattern may be satisfied with instance methods or extension methods). The requirements for the pattern are:

- The enumerable must expose a `GetAsyncEnumerator` method that may be called with no arguments and that returns an enumerator that meets the relevant pattern.
- The enumerator must expose a `MoveNextAsync` method that may be called with no arguments and that returns something which may be `await`ed and whose `GetResult()` returns a `bool`.
- The enumerator must also expose `Current` property whose getter returns a `T` representing the kind of data being enumerated.
- The enumerator may optionally expose a `DisposeAsync` method that may be invoked with no arguments and that returns something that can be `await`ed and whose `GetResult()` returns `void`.

This code:

```
var enumerable = ...;
await foreach (T item in enumerable)
{
    ...
}
```

is translated to the equivalent of:

```
var enumerable = ...;
var enumerator = enumerable.GetAsyncEnumerator();
try
{
    while (await enumerator.MoveNextAsync())
    {
        T item = enumerator.Current;
        ...
    }
}
finally
{
    await enumerator.DisposeAsync(); // omitted, along with the try/finally, if the enumerator doesn't
    expose DisposeAsync
}
```

If the iterated type doesn't expose the right pattern, the interfaces will be used.

ConfigureAwait

This pattern-based compilation will allow `ConfigureAwait` to be used on all of the awaits, via a `ConfigureAwait` extension method:

```

await foreach (T item in enumerable.ConfigureAwait(false))
{
    ...
}

```

This will be based on types we'll add to .NET as well, likely to `System.Threading.Tasks.Extensions.dll`:

```

// Approximate implementation, omitting arg validation and the like
namespace System.Threading.Tasks
{
    public static class AsyncEnumerableExtensions
    {
        public static ConfiguredAsyncEnumerable<T> ConfigureAwait<T>(this IAsyncEnumerable<T> enumerable,
bool continueOnCapturedContext) =>
            new ConfiguredAsyncEnumerable<T>(enumerable, continueOnCapturedContext);

        public struct ConfiguredAsyncEnumerable<T>
        {
            private readonly IAsyncEnumerable<T> _enumerable;
            private readonly bool _continueOnCapturedContext;

            internal ConfiguredAsyncEnumerable(IAsyncEnumerable<T> enumerable, bool
continueOnCapturedContext)
            {
                _enumerable = enumerable;
                _continueOnCapturedContext = continueOnCapturedContext;
            }

            public ConfiguredAsyncEnumerator<T> GetAsyncEnumerator() =>
                new ConfiguredAsyncEnumerator<T>(_enumerable.GetAsyncEnumerator(),
_continueOnCapturedContext);

            public struct Enumerator
            {
                private readonly IAsyncEnumerator<T> _enumerator;
                private readonly bool _continueOnCapturedContext;

                internal Enumerator(IAsyncEnumerator<T> enumerator, bool continueOnCapturedContext)
                {
                    _enumerator = enumerator;
                    _continueOnCapturedContext = continueOnCapturedContext;
                }

                public ConfiguredValueTaskAwaitable<bool> MoveNextAsync() =>
                    _enumerator.MoveNextAsync().ConfigureAwait(_continueOnCapturedContext);

                public T Current => _enumerator.Current;

                public ConfiguredValueTaskAwaitable DisposeAsync() =>
                    _enumerator.DisposeAsync().ConfigureAwait(_continueOnCapturedContext);
            }
        }
    }
}

```

Note that this approach will not enable `ConfigureAwait` to be used with pattern-based enumerables, but then again it's already the case that the `ConfigureAwait` is only exposed as an extension on `Task` / `Task<T>` / `ValueTask` / `ValueTask<T>` and can't be applied to arbitrary awaitable things, as it only makes sense when applied to Tasks (it controls a behavior implemented in Task's continuation support), and thus doesn't make sense when using a pattern where the awaitable things may not be tasks. Anyone returning awaitable things can provide their own custom behavior in such advanced scenarios.

(If we can come up with some way to support a scope- or assembly-level `ConfigureAwait` solution, then this

won't be necessary.)

Async Iterators

The language / compiler will support producing `IAsyncEnumerable<T>` s and `IAsyncEnumerator<T>` s in addition to consuming them. Today the language supports writing an iterator like:

```
static IEnumerable<int> MyIterator()
{
    try
    {
        for (int i = 0; i < 100; i++)
        {
            Thread.Sleep(1000);
            yield return i;
        }
    }
    finally
    {
        Thread.Sleep(200);
        Console.WriteLine("finally");
    }
}
```

but `await` can't be used in the body of these iterators. We will add that support.

Syntax

The existing language support for iterators infers the iterator nature of the method based on whether it contains any `yield` s. The same will be true for async iterators. Such async iterators will be demarcated and differentiated from synchronous iterators via adding `async` to the signature, and must then also have either `IAsyncEnumerable<T>` or `IAsyncEnumerator<T>` as its return type. For example, the above example could be written as an async iterator as follows:

```
static async IAsyncEnumerable<int> MyIterator()
{
    try
    {
        for (int i = 0; i < 100; i++)
        {
            await Task.Delay(1000);
            yield return i;
        }
    }
    finally
    {
        await Task.Delay(200);
        Console.WriteLine("finally");
    }
}
```

Alternatives considered:

- *Not using `async` in the signature.* Using `async` is likely technically required by the compiler, as it uses it to determine whether `await` is valid in that context. But even if it's not required, we've established that `await` may only be used in methods marked as `async`, and it seems important to keep the consistency.
- *Enabling custom builders for `IAsyncEnumerable<T>`.* That's something we could look at for the future, but the machinery is complicated and we don't support that for the synchronous counterparts.
- *Having an `iterator` keyword in the signature.* Async iterators would use `async iterator` in the signature, and `yield` could only be used in `async` methods that included `iterator`; `iterator` would then be made

optional on synchronous iterators. Depending on your perspective, this has the benefit of making it very clear by the signature of the method whether `yield` is allowed and whether the method is actually meant to return instances of type `IAsyncEnumerable<T>` rather than the compiler manufacturing one based on whether the code uses `yield` or not. But it is different from synchronous iterators, which don't and can't be made to require one. Plus some developers don't like the extra syntax. If we were designing it from scratch, we'd probably make this required, but at this point there's much more value in keeping async iterators close to sync iterators.

LINQ

There are over ~200 overloads of methods on the `System.Linq.Enumerable` class, all of which work in terms of `IEnumerable<T>`; some of these accept `IEnumerable<T>`, some of them produce `IEnumerable<T>`, and many do both. Adding LINQ support for `IAsyncEnumerable<T>` would likely entail duplicating all of these overloads for it, for another ~200. And since `IAsyncEnumerator<T>` is likely to be more common as a standalone entity in the asynchronous world than `IEnumerator<T>` is in the synchronous world, we could potentially need another ~200 overloads that work with `IAsyncEnumerator<T>`. Plus, a large number of the overloads deal with predicates (e.g. `Where` that takes a `Func<T, bool>`), and it may be desirable to have `IAsyncEnumerable<T>`-based overloads that deal with both synchronous and asynchronous predicates (e.g. `Func<T, ValueTask<bool>>` in addition to `Func<T, bool>`). While this isn't applicable to all of the now ~400 new overloads, a rough calculation is that it'd be applicable to half, which means another ~200 overloads, for a total of ~600 new methods.

That is a staggering number of APIs, with the potential for even more when extension libraries like Interactive Extensions (Ix) are considered. But Ix already has an implementation of many of these, and there doesn't seem to be a great reason to duplicate that work; we should instead help the community improve Ix and recommend it for when developers want to use LINQ with `IAsyncEnumerable<T>`.

There is also the issue of query comprehension syntax. The pattern-based nature of query comprehensions would allow them to "just work" with some operators, e.g. if Ix provides the following methods:

```
public static IAsyncEnumerable<TResult> Select<TSource, TResult>(this IAsyncEnumerable<TSource> source,
    Func<TSource, TResult> func);
public static IAsyncEnumerable<T> Where(this IAsyncEnumerable<T> source, Func<T, bool> func);
```

then this C# code will "just work":

```
IAsyncEnumerable<int> enumerable = ...;
IAsyncEnumerable<int> result = from item in enumerable
    where item % 2 == 0
    select item * 2;
```

However, there is no query comprehension syntax that supports using `await` in the clauses, so if Ix added, for example:

```
public static IAsyncEnumerable<TResult> Select<TSource, TResult>(this IAsyncEnumerable<TSource> source,
    Func<TSource, ValueTask<TResult>> func);
```

then this would "just work":

```

IEnumerable<string> result = from url in urls
                             where item % 2 == 0
                             select SomeAsyncMethod(item);

async ValueTask<int> SomeAsyncMethod(int item)
{
    await Task.Yield();
    return item * 2;
}

```

but there'd be no way to write it with the `await` inline in the `select` clause. As a separate effort, we could look into adding `async { ... }` expressions to the language, at which point we could allow them to be used in query comprehensions and the above could instead be written as:

```

IEnumerable<int> result = from item in enumerable
                         where item % 2 == 0
                         select async
                        {
                            await Task.Yield();
                            return item * 2;
                        };

```

or to enabling `await` to be used directly in expressions, such as by supporting `async from`. However, it's unlikely a design here would impact the rest of the feature set one way or the other, and this isn't a particularly high-value thing to invest in right now, so the proposal is to do nothing additional here right now.

Integration with other asynchronous frameworks

Integration with `IObservable<T>` and other asynchronous frameworks (e.g. reactive streams) would be done at the library level rather than at the language level. For example, all of the data from an `IAsyncEnumerator<T>` can be published to an `IObserver<T>` simply by `await foreach`'ing over the enumerator and `OnNext`'ing the data to the observer, so an `AsObservable<T>` extension method is possible. Consuming an `IObservable<T>` in a `await foreach` requires buffering the data (in case another item is pushed while the previous item is still being processing), but such a push-pull adapter can easily be implemented to enable an `IObservable<T>` to be pulled from with an `IAsyncEnumerator<T>`. Etc. Rx/lx already provide prototypes of such implementations, and libraries like <https://github.com/dotnet/corefx/tree/master/src/System.Threading.Channels> provide various kinds of buffering data structures. The language need not be involved at this stage.

Ranges

12/28/2021 • 12 minutes to read • [Edit Online](#)

Summary

This feature is about delivering two new operators that allow constructing `System.Index` and `System.Range` objects, and using them to index/slice collections at runtime.

Overview

Well-known types and members

To use the new syntactic forms for `System.Index` and `System.Range`, new well-known types and members may be necessary, depending on which syntactic forms are used.

To use the "hat" operator (`^`), the following is required

```
namespace System
{
    public readonly struct Index
    {
        public Index(int value, bool fromEnd);
    }
}
```

To use the `System.Index` type as an argument in an array element access, the following member is required:

```
int System.Index.GetOffset(int length);
```

The `..` syntax for `System.Range` will require the `System.Range` type, as well as one or more of the following members:

```
namespace System
{
    public readonly struct Range
    {
        public Range(System.Index start, System.Index end);
        public static Range StartAt(System.Index start);
        public static Range EndAt(System.Index end);
        public static Range All { get; }
    }
}
```

The `..` syntax allows for either, both, or none of its arguments to be absent. Regardless of the number of arguments, the `Range` constructor is always sufficient for using the `Range` syntax. However, if any of the other members are present and one or more of the `..` arguments are missing, the appropriate member may be substituted.

Finally, for a value of type `System.Range` to be used in an array element access expression, the following member must be present:

```
namespace System.Runtime.CompilerServices
{
    public static class RuntimeHelpers
    {
        public static T[] GetSubArray<T>(T[] array, System.Range range);
    }
}
```

System.Index

C# has no way of indexing a collection from the end, but rather most indexers use the "from start" notion, or do a "length - i" expression. We introduce a new Index expression that means "from the end". The feature will introduce a new unary prefix "hat" operator. Its single operand must be convertible to `System.Int32`. It will be lowered into the appropriate `System.Index` factory method call.

We augment the grammar for *unary_expression* with the following additional syntax form:

```
unary_expression
: '^' unary_expression
;
```

We call this the *index from end* operator. The predefined *index from end* operators are as follows:

```
System.Index operator ^(int fromEnd);
```

The behavior of this operator is only defined for input values greater than or equal to zero.

Examples:

```
var array = new int[] { 1, 2, 3, 4, 5 };
var thirdItem = array[2];    // array[2]
var lastItem = array[^1];    // array[new Index(1, fromEnd: true)]
```

System.Range

C# has no syntactic way to access "ranges" or "slices" of collections. Usually users are forced to implement complex structures to filter/operate on slices of memory, or resort to LINQ methods like `list.Skip(5).Take(2)`. With the addition of `System.Span<T>` and other similar types, it becomes more important to have this kind of operation supported on a deeper level in the language/runtime, and have the interface unified.

The language will introduce a new range operator `x..y`. It is a binary infix operator that accepts two expressions. Either operand can be omitted (examples below), and they have to be convertible to `System.Index`. It will be lowered to the appropriate `System.Range` factory method call.

We replace the C# grammar rules for *multiplicative_expression* with the following (in order to introduce a new precedence level):

```

range_expression
: unary_expression
| range_expression? '..' range_expression?
;

multiplicative_expression
: range_expression
| multiplicative_expression '*' range_expression
| multiplicative_expression '/' range_expression
| multiplicative_expression '%' range_expression
;

```

All forms of the *range operator* have the same precedence. This new precedence group is lower than the *unary operators* and higher than the *multiplicative arithmetic operators*.

We call the `..` operator the *range operator*. The built-in range operator can roughly be understood to correspond to the invocation of a built-in operator of this form:

```
System.Range operator ..(Index start = 0, Index end = ^0);
```

Examples:

```

var array = new int[] { 1, 2, 3, 4, 5 };
var slice1 = array[2..^3];    // array[new Range(2, new Index(3, fromEnd: true))]
var slice2 = array[..^3];    // array[Range.EndAt(new Index(3, fromEnd: true))]
var slice3 = array[2..];     // array[Range.StartAt(2)]
var slice4 = array[..];      // array[Range.All]

```

Moreover, `System.Index` should have an implicit conversion from `System.Int32`, in order to avoid the need to overload mixing integers and indexes over multi-dimensional signatures.

Adding Index and Range support to existing library types

Implicit Index support

The language will provide an instance indexer member with a single parameter of type `Index` for types which meet the following criteria:

- The type is `Countable`.
- The type has an accessible instance indexer which takes a single `int` as the argument.
- The type does not have an accessible instance indexer which takes an `Index` as the first parameter. The `Index` must be the only parameter or the remaining parameters must be optional.

A type is ***Countable*** if it has a property named `Length` or `Count` with an accessible getter and a return type of `int`. The language can make use of this property to convert an expression of type `Index` into an `int` at the point of the expression without the need to use the type `Index` at all. In case both `Length` and `Count` are present, `Length` will be preferred. For simplicity going forward, the proposal will use the name `Length` to represent `Count` or `Length`.

For such types, the language will act as if there is an indexer member of the form `T this[Index index]` where `T` is the return type of the `int` based indexer including any `ref` style annotations. The new member will have the same `get` and `set` members with matching accessibility as the `int` indexer.

The new indexer will be implemented by converting the argument of type `Index` into an `int` and emitting a call to the `int` based indexer. For discussion purposes, let's use the example of `receiver[expr]`. The conversion of `expr` to `int` will occur as follows:

- When the argument is of the form `^expr2` and the type of `expr2` is `int`, it will be translated to `receiver.Length - expr2`.
- Otherwise, it will be translated as `expr.GetOffset(receiver.Length)`.

Regardless of the specific conversion strategy, the order of evaluation should be equivalent to the following:

1. `receiver` is evaluated;
2. `expr` is evaluated;
3. `length` is evaluated, if needed;
4. the `int` based indexer is invoked.

This allows for developers to use the `Index` feature on existing types without the need for modification. For example:

```
List<char> list = ...;
var value = list[^1];

// Gets translated to
var value = list[list.Count - 1];
```

The `receiver` and `Length` expressions will be spilled as appropriate to ensure any side effects are only executed once. For example:

```
class Collection {
    private int[] _array = new[] { 1, 2, 3 };

    public int Length {
        get {
            Console.WriteLine("Length ");
            return _array.Length;
        }
    }

    public int this[int index] => _array[index];
}

class SideEffect {
    Collection Get() {
        Console.WriteLine("Get ");
        return new Collection();
    }

    void Use() {
        int i = Get()[^1];
        Console.WriteLine(i);
    }
}
```

This code will print "Get Length 3".

Implicit Range support

The language will provide an instance indexer member with a single parameter of type `Range` for types which meet the following criteria:

- The type is Countable.
- The type has an accessible member named `Slice` which has two parameters of type `int`.
- The type does not have an instance indexer which takes a single `Range` as the first parameter. The `Range` must be the only parameter or the remaining parameters must be optional.

For such types, the language will bind as if there is an indexer member of the form `T this[Range range]` where `T` is the return type of the `Slice` method including any `ref` style annotations. The new member will also have matching accessibility with `Slice`.

When the `Range` based indexer is bound on an expression named `receiver`, it will be lowered by converting the `Range` expression into two values that are then passed to the `Slice` method. For discussion purposes, let's use the example of `receiver[expr]`.

The first argument of `Slice` will be obtained by converting the range typed expression in the following way:

- When `expr` is of the form `expr1..expr2` (where `expr2` can be omitted) and `expr1` has type `int`, then it will be emitted as `expr1`.
- When `expr` is of the form `^expr1..expr2` (where `expr2` can be omitted), then it will be emitted as `receiver.Length - expr1`.
- When `expr` is of the form `..expr2` (where `expr2` can be omitted), then it will be emitted as `0`.
- Otherwise, it will be emitted as `expr.Start.GetOffset(receiver.Length)`.

This value will be re-used in the calculation of the second `Slice` argument. When doing so it will be referred to as `start`. The second argument of `Slice` will be obtained by converting the range typed expression in the following way:

- When `expr` is of the form `expr1..expr2` (where `expr1` can be omitted) and `expr2` has type `int`, then it will be emitted as `expr2 - start`.
- When `expr` is of the form `expr1..^expr2` (where `expr1` can be omitted), then it will be emitted as `(receiver.Length - expr2) - start`.
- When `expr` is of the form `expr1..` (where `expr1` can be omitted), then it will be emitted as `receiver.Length - start`.
- Otherwise, it will be emitted as `expr.End.GetOffset(receiver.Length) - start`.

Regardless of the specific conversion strategy, the order of evaluation should be equivalent to the following:

1. `receiver` is evaluated;
2. `expr` is evaluated;
3. `length` is evaluated, if needed;
4. the `Slice` method is invoked.

The `receiver`, `expr`, and `length` expressions will be spilled as appropriate to ensure any side effects are only executed once. For example:

```

class Collection {
    private int[] _array = new[] { 1, 2, 3 };

    public int Length {
        get {
            Console.Write("Length ");
            return _array.Length;
        }
    }

    public int[] Slice(int start, int length) {
        var slice = new int[length];
        Array.Copy(_array, start, slice, 0, length);
        return slice;
    }
}

class SideEffect {
    Collection Get() {
        Console.Write("Get ");
        return new Collection();
    }

    void Use() {
        var array = Get()[0..2];
        Console.WriteLine(array.Length);
    }
}

```

This code will print "Get Length 2".

The language will special case the following known types:

- `string`: the method `Substring` will be used instead of `Slice`.
- `array`: the method `System.Runtime.CompilerServices.RuntimeHelpers.GetSubArray` will be used instead of `Slice`.

Alternatives

The new operators (`^` and `..`) are syntactic sugar. The functionality can be implemented by explicit calls to `System.Index` and `System.Range` factory methods, but it will result in a lot more boilerplate code, and the experience will be unintuitive.

IL Representation

These two operators will be lowered to regular indexer/method calls, with no change in subsequent compiler layers.

Runtime behavior

- Compiler can optimize indexers for built-in types like arrays and strings, and lower the indexing to the appropriate existing methods.
- `System.Index` will throw if constructed with a negative value.
- `^0` does not throw, but it translates to the length of the collection/enumerable it is supplied to.
- `Range.All` is semantically equivalent to `0..^0`, and can be deconstructed to these indices.

Considerations

Detect Indexable based on ICollection

The inspiration for this behavior was collection initializers. Using the structure of a type to convey that it had opted into a feature. In the case of collection initializers types can opt into the feature by implementing the interface `IEnumerable` (non generic).

This proposal initially required that types implement `ICollection` in order to qualify as Indexable. That required a number of special cases though:

- `ref struct`: these cannot implement interfaces yet types like `Span<T>` are ideal for index / range support.
- `string`: does not implement `ICollection` and adding that `interface` has a large cost.

This means to support key types special casing is already needed. The special casing of `string` is less interesting as the language does this in other areas (`foreach` lowering, constants, etc ...). The special casing of `ref struct` is more concerning as it's special casing an entire class of types. They get labeled as Indexable if they simply have a property named `Count` with a return type of `int`.

After consideration the design was normalized to say that any type which has a property `Count` / `Length` with a return type of `int` is Indexable. That removes all special casing, even for `string` and arrays.

Detect just Count

Detecting on the property names `Count` or `Length` does complicate the design a bit. Picking just one to standardize though is not sufficient as it ends up excluding a large number of types:

- Use `Length`: excludes pretty much every collection in `System.Collections` and sub-namespaces. Those tend to derive from `ICollection` and hence prefer `Count` over `length`.
- Use `Count`: excludes `string`, arrays, `Span<T>` and most `ref struct` based types

The extra complication on the initial detection of Indexable types is outweighed by its simplification in other aspects.

Choice of Slice as a name

The name `Slice` was chosen as it's the de-facto standard name for slice style operations in .NET. Starting with `netcoreapp2.1` all span style types use the name `Slice` for slicing operations. Prior to `netcoreapp2.1` there really aren't any examples of slicing to look to for an example. Types like `List<T>`, `ArraySegment<T>`, `SortedList<T>` would've been ideal for slicing but the concept didn't exist when types were added.

Thus, `Slice` being the sole example, it was chosen as the name.

Index target type conversion

Another way to view the `Index` transformation in an indexer expression is as a target type conversion. Instead of binding as if there is a member of the form `return_type this[Index]`, the language instead assigns a target typed conversion to `int`.

This concept could be generalized to all member access on Countable types. Whenever an expression with type `Index` is used as an argument to an instance member invocation and the receiver is Countable then the expression will have a target type conversion to `int`. The member invocations applicable for this conversion include methods, indexers, properties, extension methods, etc ... Only constructors are excluded as they have no receiver.

The target type conversion will be implemented as follows for any expression which has a type of `Index`. For discussion purposes lets use the example of `receiver[expr]`:

- When `expr` is of the form `^expr2` and the type of `expr2` is `int`, it will be translated to `receiver.Length - expr2`.
- Otherwise, it will be translated as `expr.GetOffset(receiver.Length)`.

The `receiver` and `Length` expressions will be spilled as appropriate to ensure any side effects are only executed once. For example:

```
class Collection {
    private int[] _array = new[] { 1, 2, 3 };

    public int Length {
        get {
            Console.Write("Length ");
            return _array.Length;
        }
    }

    public int GetAt(int index) => _array[index];
}

class SideEffect {
    Collection Get() {
        Console.Write("Get ");
        return new Collection();
    }

    void Use() {
        int i = Get().GetAt(^1);
        Console.WriteLine(i);
    }
}
```

This code will print "Get Length 3".

This feature would be beneficial to any member which had a parameter that represented an index. For example `List<T>.InsertAt`. This also has the potential for confusion as the language can't give any guidance as to whether or not an expression is meant for indexing. All it can do is convert any `Index` expression to `int` when invoking a member on a Countable type.

Restrictions:

- This conversion is only applicable when the expression with type `Index` is directly an argument to the member. It would not apply to any nested expressions.

Decisions made during implementation

- All members in the pattern must be instance members
- If a Length method is found but it has the wrong return type, continue looking for Count
- The indexer used for the Index pattern must have exactly one int parameter
- The Slice method used for the Range pattern must have exactly two int parameters
- When looking for the pattern members, we look for original definitions, not constructed members

"pattern-based using" and "using declarations"

12/28/2021 • 4 minutes to read • [Edit Online](#)

Summary

The language will add two new capabilities around the `using` statement in order to make resource management simpler: `using` should recognize a disposable pattern in addition to `IDisposable` and add a `using` declaration to the language.

Motivation

The `using` statement is an effective tool for resource management today but it requires quite a bit of ceremony. Methods that have a number of resources to manage can get syntactically bogged down with a series of `using` statements. This syntax burden is enough that most coding style guidelines explicitly have an exception around braces for this scenario.

The `using` declaration removes much of the ceremony here and gets C# on par with other languages that include resource management blocks. Additionally the pattern-based `using` lets developers expand the set of types that can participate here. In many cases removing the need to create wrapper types that only exist to allow for a values use in a `using` statement.

Together these features allow developers to simplify and expand the scenarios where `using` can be applied.

Detailed Design

using declaration

The language will allow for `using` to be added to a local variable declaration. Such a declaration will have the same effect as declaring the variable in a `using` statement at the same location.

```
if (...)
{
    using FileStream f = new FileStream(@"C:\users\jaredpar\using.md");
    // statements
}

// Equivalent to
if (...)
{
    using (FileStream f = new FileStream(@"C:\users\jaredpar\using.md"))
    {
        // statements
    }
}
```

The lifetime of a `using` local will extend to the end of the scope in which it is declared. The `using` locals will then be disposed in the reverse order in which they are declared.

```

{
    using var f1 = new FileStream("...");
    using var f2 = new FileStream("..."), f3 = new FileStream("...");
    ...
    // Dispose f3
    // Dispose f2
    // Dispose f1
}

```

There are no restrictions around `goto`, or any other control flow construct in the face of a `using` declaration. Instead the code acts just as it would for the equivalent `using` statement:

```

{
    using var f1 = new FileStream("...");
target:
    using var f2 = new FileStream("...");
    if (someCondition)
    {
        // Causes f2 to be disposed but has no effect on f1
        goto target;
    }
}

```

A local declared in a `using` local declaration will be implicitly read-only. This matches the behavior of locals declared in a `using` statement.

The language grammar for `using` declarations will be the following:

```

local-using-declaration:
    using type using-declarators

using-declarators:
    using-declarator
    using-declarators , using-declarator

using-declarator:
    identifier = expression

```

Restrictions around `using` declaration:

- May not appear directly inside a `case` label but instead must be within a block inside the `case` label.
- May not appear as part of an `out` variable declaration.
- Must have an initializer for each declarator.
- The local type must be implicitly convertible to `IDisposable` or fulfill the `using` pattern.

pattern-based using

The language will add the notion of a disposable pattern: that is a type which has an accessible `Dispose` instance method. Types which fit the disposable pattern can participate in a `using` statement or declaration without being required to implement `IDisposable`.

```

class Resource
{
    public void Dispose() { ... }
}

using (var r = new Resource())
{
    // statements
}

```

This will allow developers to leverage `using` in a number of new scenarios:

- `ref struct`: These types can't implement interfaces today and hence can't participate in `using` statements.
- Extension methods will allow developers to augment types in other assemblies to participate in `using` statements.

In the situation where a type can be implicitly converted to `IDisposable` and also fits the disposable pattern, then `IDisposable` will be preferred. While this takes the opposite approach of `foreach` (pattern preferred over interface) it is necessary for backwards compatibility.

The same restrictions from a traditional `using` statement apply here as well: local variables declared in the `using` are read-only, a `null` value will not cause an exception to be thrown, etc ... The code generation will be different only in that there will not be a cast to `IDisposable` before calling `Dispose`:

```

{
    Resource r = new Resource();
    try {
        // statements
    }
    finally {
        if (r != null) r.Dispose();
    }
}

```

In order to fit the disposable pattern the `Dispose` method must be accessible, parameterless and have a `void` return type. There are no other restrictions. This explicitly means that extension methods can be used here.

Considerations

case labels without blocks

A `using declaration` is illegal directly inside a `case` label due to complications around its actual lifetime. One potential solution is to simply give it the same lifetime as an `out var` in the same location. It was deemed the extra complexity to the feature implementation and the ease of the work around (just add a block to the `case` label) didn't justify taking this route.

Future Expansions

fixed locals

A `fixed` statement has all of the properties of `using` statements that motivated the ability to have `using` locals. Consideration should be given to extending this feature to `fixed` locals as well. The lifetime and ordering rules should apply equally well for `using` and `fixed` here.

Static local functions

12/28/2021 • 2 minutes to read • [Edit Online](#)

Summary

Support local functions that disallow capturing state from the enclosing scope.

Motivation

Avoid unintentionally capturing state from the enclosing context. Allow local functions to be used in scenarios where a `static` method is required.

Detailed design

A local function declared `static` cannot capture state from the enclosing scope. As a result, locals, parameters, and `this` from the enclosing scope are not available within a `static` local function.

A `static` local function cannot reference instance members from an implicit or explicit `this` or `base` reference.

A `static` local function may reference `static` members from the enclosing scope.

A `static` local function may reference `constant` definitions from the enclosing scope.

`nameof()` in a `static` local function may reference locals, parameters, or `this` or `base` from the enclosing scope.

Accessibility rules for `private` members in the enclosing scope are the same for `static` and non-`static` local functions.

A `static` local function definition is emitted as a `static` method in metadata, even if only used in a delegate.

A non-`static` local function or lambda can capture state from an enclosing `static` local function but cannot capture state outside the enclosing `static` local function.

A `static` local function cannot be invoked in an expression tree.

A call to a local function is emitted as `call` rather than `callvirt`, regardless of whether the local function is `static`.

Overload resolution of a call within a local function not affected by whether the local function is `static`.

Removing the `static` modifier from a local function in a valid program does not change the meaning of the program.

null coalescing assignment

12/28/2021 • 2 minutes to read • [Edit Online](#)

Summary

Simplifies a common coding pattern where a variable is assigned a value if it is null.

As part of this proposal, we will also loosen the type requirements on `??` to allow an expression whose type is an unconstrained type parameter to be used on the left-hand side.

Motivation

It is common to see code of the form

```
if (variable == null)
{
    variable = expression;
}
```

This proposal adds a non-overloadable binary operator to the language that performs this function.

There have been at least eight separate community requests for this feature.

Detailed design

We add a new form of assignment operator

```
assignment_operator
: '??='
;
```

Which follows the [existing semantic rules for compound assignment operators](#), except that we elide the assignment if the left-hand side is non-null. The rules for this feature are as follows.

Given `a ??= b`, where `A` is the type of `a`, `B` is the type of `b`, and `A0` is the underlying type of `A` if `A` is a nullable value type:

1. If `A` does not exist or is a non-nullable value type, a compile-time error occurs.
2. If `B` is not implicitly convertible to `A` or `A0` (if `A0` exists), a compile-time error occurs.
3. If `A0` exists and `B` is implicitly convertible to `A0`, and `B` is not dynamic, then the type of `a ??= b` is `A0`.

`a ??= b` is evaluated at runtime as:

```
var tmp = a.GetValueOrDefault();
if (!a.HasValue) { tmp = b; a = tmp; }
tmp
```

Except that `a` is only evaluated once.

4. Otherwise, the type of `a ??= b` is `A`. `a ??= b` is evaluated at runtime as `a ?? (a = b)`, except that `a` is only evaluated once.

For the relaxation of the type requirements of `??`, we update the spec where it currently states that, given

`a ?? b`, where `A` is the type of `a`:

1. If `A` exists and is not a nullable type or a reference type, a compile-time error occurs.

We relax this requirement to:

1. If `A` exists and is a non-nullable value type, a compile-time error occurs.

This allows the null coalescing operator to work on unconstrained type parameters, as the unconstrained type parameter `T` exists, is not a nullable type, and is not a reference type.

Drawbacks

As with any language feature, we must question whether the additional complexity to the language is repaid in the additional clarity offered to the body of C# programs that would benefit from the feature.

Alternatives

The programmer can write `(x = x ?? y)`, `if (x == null) x = y;`, or `x ?? (x = y)` by hand.

Unresolved questions

- [] Requires LDM review
- [] Should we also support `&&=` and `||=` operators?

Design meetings

None.

Readonly Instance Members

12/28/2021 • 4 minutes to read • [Edit Online](#)

Championed Issue: <https://github.com/dotnet/csharplang/issues/1710>

Summary

Provide a way to specify individual instance members on a struct do not modify state, in the same way that `readonly struct` specifies no instance members modify state.

It is worth noting that `readonly instance member` \neq `pure instance member`. A `pure` instance member guarantees no state will be modified. A `readonly` instance member only guarantees that instance state will not be modified.

All instance members on a `readonly struct` could be considered implicitly `readonly instance members`. Explicit `readonly instance members` declared on non-readonly structs would behave in the same manner. For example, they would still create hidden copies if you called an instance member (on the current instance or on a field of the instance) which was itself not-readonly.

Motivation

Today, users have the ability to create `readonly struct` types which the compiler enforces that all fields are readonly (and by extension, that no instance members modify the state). However, there are some scenarios where you have an existing API that exposes accessible fields or that has a mix of mutating and non-mutating members. Under these circumstances, you cannot mark the type as `readonly` (it would be a breaking change).

This normally doesn't have much impact, except in the case of `in` parameters. With `in` parameters for non-readonly structs, the compiler will make a copy of the parameter for each instance member invocation, since it cannot guarantee that the invocation does not modify internal state. This can lead to a multitude of copies and worse overall performance than if you had just passed the struct directly by value. For an example, see this code on [sharplab](#)

Some other scenarios where hidden copies can occur include `static readonly fields` and `literals`. If they are supported in the future, `blittable constants` would end up in the same boat; that is they all currently necessitate a full copy (on instance member invocation) if the struct is not marked `readonly`.

Design

Allow a user to specify that an instance member is, itself, `readonly` and does not modify the state of the instance (with all the appropriate verification done by the compiler, of course). For example:

```

public struct Vector2
{
    public float x;
    public float y;

    public readonly float GetLengthReadOnly()
    {
        return MathF.Sqrt(LengthSquared);
    }

    public float GetLength()
    {
        return MathF.Sqrt(LengthSquared);
    }

    public readonly float GetLengthIllegal()
    {
        var tmp = MathF.Sqrt(LengthSquared);

        x = tmp;    // Compiler error, cannot write x
        y = tmp;    // Compiler error, cannot write y

        return tmp;
    }

    public readonly float LengthSquared
    {
        get
        {
            return (x * x) +
                   (y * y);
        }
    }
}

public static class MyClass
{
    public static float ExistingBehavior(in Vector2 vector)
    {
        // This code causes a hidden copy, the compiler effectively emits:
        //     var tmpVector = vector;
        //     return tmpVector.GetLength();
        //
        // This is done because the compiler doesn't know that `GetLength()`
        // won't mutate `vector`.

        return vector.GetLength();
    }

    public static float ReadOnlyBehavior(in Vector2 vector)
    {
        // This code is emitted exactly as listed. There are no hidden
        // copies as the `readonly` modifier indicates that the method
        // won't mutate `vector`.

        return vector.GetLengthReadOnly();
    }
}

```

ReadOnly can be applied to property accessors to indicate that `this` will not be mutated in the accessor. The following examples have readonly setters because those accessors modify the state of member field, but do not modify the value of that member field.

```
public readonly int Prop1
{
    get
    {
        return this._store["Prop1"];
    }
    set
    {
        this._store["Prop1"] = value;
    }
}
```

When `readonly` is applied to the property syntax, it means that all accessors are `readonly`.

```
public readonly int Prop2
{
    get
    {
        return this._store["Prop2"];
    }
    set
    {
        this._store["Prop2"] = value;
    }
}
```

Readonly can only be applied to accessors which do not mutate the containing type.

```
public int Prop3
{
    readonly get
    {
        return this._prop3;
    }
    set
    {
        this._prop3 = value;
    }
}
```

Readonly can be applied to some auto-implemented properties, but it won't have a meaningful effect. The compiler will treat all auto-implemented getters as readonly whether or not the `readonly` keyword is present.

```
// Allowed
public readonly int Prop4 { get; }
public int Prop5 { readonly get; }
public int Prop6 { readonly get; set; }

// Not allowed
public readonly int Prop7 { get; set; }
public int Prop8 { get; readonly set; }
```

Readonly can be applied to manually-implemented events, but not field-like events. Readonly cannot be applied to individual event accessors (add/remove).

```
// Allowed
public readonly event Action<EventArgs> Event1
{
    add { }
    remove { }
}

// Not allowed
public readonly event Action<EventArgs> Event2;
public event Action<EventArgs> Event3
{
    readonly add { }
    readonly remove { }
}
public static readonly event Event4
{
    add { }
    remove { }
}
```

Some other syntax examples:

- Expression bodied members: `public readonly float ExpressionBodiedMember => (x * x) + (y * y);`
- Generic constraints: `public readonly void GenericMethod<T>(T value) where T : struct { }`

The compiler would emit the instance member, as usual, and would additionally emit a compiler recognized attribute indicating that the instance member does not modify state. This effectively causes the hidden `this` parameter to become `in T` instead of `ref T`.

This would allow the user to safely call said instance method without the compiler needing to make a copy.

The restrictions would include:

- The `readonly` modifier cannot be applied to static methods, constructors or destructors.
- The `readonly` modifier cannot be applied to delegates.
- The `readonly` modifier cannot be applied to members of class or interface.

Drawbacks

Same drawbacks as exist with `readonly struct` methods today. Certain code may still cause hidden copies.

Notes

Using an attribute or another keyword may also be possible.

This proposal is somewhat related to (but is more a subset of) `functional purity` and/or `constant expressions`, both of which have had some existing proposals.

Permit `stackalloc` in nested contexts

12/28/2021 • 2 minutes to read • [Edit Online](#)

Stack allocation

We modify the section *Stack allocation* of the C# language specification to relax the places when a `stackalloc` expression may appear. We delete

```
local_variable_initializer_unsafe
    : stackalloc_initializer
    ;

stackalloc_initializer
    : 'stackalloc' unmanaged_type '[' expression ']'
    ;
```

and replace them with

```
primary_no_array_creation_expression
    : stackalloc_initializer
    ;

stackalloc_initializer
    : 'stackalloc' unmanaged_type '[' expression? ']' array_initializer?
    | 'stackalloc' '[' expression? ']' array_initializer
    ;
```

Note that the addition of an *array_initializer* to *stackalloc_initializer* (and making the index expression optional) was an [extension in C# 7.3](#) and is not described here.

The *element type* of the `stackalloc` expression is the *unmanaged_type* named in the *stackalloc* expression, if any, or the common type among the elements of the *array_initializer* otherwise.

The type of the *stackalloc_initializer* with *element type* `K` depends on its syntactic context:

- If the *stackalloc_initializer* appears directly as the *local_variable_initializer* of a *local_variable_declaration* statement or a *for_initializer*, then its type is `K*`.
- Otherwise its type is `System.Span<K>`.

Stackalloc Conversion

The *stackalloc conversion* is a new built-in implicit conversion from expression. When the type of a *stackalloc_initializer* is `K*`, there is an implicit *stackalloc conversion* from the *stackalloc_initializer* to the type `System.Span<K>`.

Records

12/28/2021 • 14 minutes to read • [Edit Online](#)

This proposal tracks the specification for the C# 9 records feature, as agreed to by the C# language design team.

The syntax for a record is as follows:

```
record_declaration
    : attributes? class_modifier* 'partial'? 'record' identifier type_parameter_list?
      parameter_list? record_base? type_parameter_constraints_clause* record_body
      ;

record_base
    : ':' class_type argument_list?
    | ':' interface_type_list
    | ':' class_type argument_list? ',' interface_type_list
    ;

record_body
    : '{' class_member_declaration* '}' ';'
    | ';'
    ;
```

Record types are reference types, similar to a class declaration. It is an error for a record to provide a `record_base` `argument_list` if the `record_declaration` does not contain a `parameter_list`. At most one partial type declaration of a partial record may provide a `parameter_list`.

Record parameters cannot use `ref`, `out` or `this` modifiers (but `in` and `params` are allowed).

Inheritance

Records cannot inherit from classes, unless the class is `object`, and classes cannot inherit from records. Records can inherit from other records.

Members of a record type

In addition to the members declared in the record body, a record type has additional synthesized members. Members are synthesized unless a member with a "matching" signature is declared in the record body or an accessible concrete non-virtual member with a "matching" signature is inherited. A matching member prevents the compiler from generating that member, not any other synthesized members. Two members are considered matching if they have the same signature or would be considered "hiding" in an inheritance scenario. It is an error for a member of a record to be named "Clone". It is an error for an instance field of a record to have an unsafe type.

The synthesized members are as follows:

Equality members

If the record is derived from `object`, the record type includes a synthesized readonly property equivalent to a property declared as follows:

```
Type EqualityContract { get; };
```

The property is `private` if the record type is `sealed`. Otherwise, the property is `virtual` and `protected`. The

property can be declared explicitly. It is an error if the explicit declaration does not match the expected signature or accessibility, or if the explicit declaration doesn't allow overriding it in a derived type and the record type is not `sealed`.

If the record type is derived from a base record type `Base`, the record type includes a synthesized readonly property equivalent to a property declared as follows:

```
protected override Type EqualityContract { get; };
```

The property can be declared explicitly. It is an error if the explicit declaration does not match the expected signature or accessibility, or if the explicit declaration doesn't allow overriding it in a derived type and the record type is not `sealed`. It is an error if either synthesized, or explicitly declared property doesn't override a property with this signature in the record type `Base` (for example, if the property is missing in the `Base`, or sealed, or not virtual, etc.). The synthesized property returns `typeof(R)` where `R` is the record type.

The record type implements `System.IEquatable<R>` and includes a synthesized strongly-typed overload of `Equals(R? other)` where `R` is the record type. The method is `public`, and the method is `virtual` unless the record type is `sealed`. The method can be declared explicitly. It is an error if the explicit declaration does not match the expected signature or accessibility, or the explicit declaration doesn't allow overriding it in a derived type and the record type is not `sealed`.

If `Equals(R? other)` is user-defined (not synthesized) but `GetHashCode` is not, a warning is produced.

```
public virtual bool Equals(R? other);
```

The synthesized `Equals(R?)` returns `true` if and only if each of the following are `true`:

- `other` is not `null`, and
- For each instance field `fieldN` in the record type that is not inherited, the value of `System.Collections.Generic.EqualityComparer<TN>.Default.Equals(fieldN, other.fieldN)` where `TN` is the field type, and
- If there is a base record type, the value of `base.Equals(other)` (a non-virtual call to `public virtual bool Equals(Base? other)`); otherwise the value of `EqualityContract == other.EqualityContract`.

The record type includes synthesized `==` and `!=` operators equivalent to operators declared as follows:

```
public static bool operator==(R? left, R? right)
    => (object)left == right || (left?.Equals(right) ?? false);
public static bool operator!=(R? left, R? right)
    => !(left == right);
```

The `Equals` method called by the `==` operator is the `Equals(R? other)` method specified above. The `!=` operator delegates to the `==` operator. It is an error if the operators are declared explicitly.

If the record type is derived from a base record type `Base`, the record type includes a synthesized override equivalent to a method declared as follows:

```
public sealed override bool Equals(Base? other);
```

It is an error if the override is declared explicitly. It is an error if the method doesn't override a method with same signature in record type `Base` (for example, if the method is missing in the `Base`, or sealed, or not virtual, etc.).

The synthesized override returns `Equals((object?)other)`.

The record type includes a synthesized override equivalent to a method declared as follows:

```
public override bool Equals(object? obj);
```

It is an error if the override is declared explicitly. It is an error if the method doesn't override `object.Equals(object? obj)` (for example, due to shadowing in intermediate base types, etc.). The synthesized override returns `Equals(other as R)` where `R` is the record type.

The record type includes a synthesized override equivalent to a method declared as follows:

```
public override int GetHashCode();
```

The method can be declared explicitly. It is an error if the explicit declaration doesn't allow overriding it in a derived type and the record type is not `sealed`. It is an error if either synthesized, or explicitly declared method doesn't override `object.GetHashCode()` (for example, due to shadowing in intermediate base types, etc.).

A warning is reported if one of `Equals(R?)` and `GetHashCode()` is explicitly declared but the other method is not explicit.

The synthesized override of `GetHashCode()` returns an `int` result of combining the following values:

- For each instance field `fieldN` in the record type that is not inherited, the value of `System.Collections.Generic.EqualityComparer<TN>.Default.GetHashCode(fieldN)` where `TN` is the field type, and
- If there is a base record type, the value of `base.GetHashCode()`; otherwise the value of `System.Collections.Generic.EqualityComparer<System.Type>.Default.GetHashCode(EqualityContract)`.

For example, consider the following record types:

```
record R1(T1 P1);  
record R2(T1 P1, T2 P2) : R1(P1);  
record R3(T1 P1, T2 P2, T3 P3) : R2(P1, P2);
```

For those record types, the synthesized equality members would be something like:

```

class R1 : IEquatable<R1>
{
    public T1 P1 { get; init; }
    protected virtual Type EqualityContract => typeof(R1);
    public override bool Equals(object? obj) => Equals(obj as R1);
    public virtual bool Equals(R1? other)
    {
        return !(other is null) &&
            EqualityContract == other.EqualityContract &&
            EqualityComparer<T1>.Default.Equals(P1, other.P1);
    }
    public static bool operator==(R1? left, R1? right)
        => (object)left == right || (left?.Equals(right) ?? false);
    public static bool operator!=(R1? left, R1? right)
        => !(left == right);
    public override int GetHashCode()
    {
        return Combine(EqualityComparer<Type>.Default.GetHashCode(EqualityContract),
            EqualityComparer<T1>.Default.GetHashCode(P1));
    }
}

class R2 : R1, IEquatable<R2>
{
    public T2 P2 { get; init; }
    protected override Type EqualityContract => typeof(R2);
    public override bool Equals(object? obj) => Equals(obj as R2);
    public sealed override bool Equals(R1? other) => Equals((object?)other);
    public virtual bool Equals(R2? other)
    {
        return base.Equals((R1?)other) &&
            EqualityComparer<T2>.Default.Equals(P2, other.P2);
    }
    public static bool operator==(R2? left, R2? right)
        => (object)left == right || (left?.Equals(right) ?? false);
    public static bool operator!=(R2? left, R2? right)
        => !(left == right);
    public override int GetHashCode()
    {
        return Combine(base.GetHashCode(),
            EqualityComparer<T2>.Default.GetHashCode(P2));
    }
}

class R3 : R2, IEquatable<R3>
{
    public T3 P3 { get; init; }
    protected override Type EqualityContract => typeof(R3);
    public override bool Equals(object? obj) => Equals(obj as R3);
    public sealed override bool Equals(R2? other) => Equals((object?)other);
    public virtual bool Equals(R3? other)
    {
        return base.Equals((R2?)other) &&
            EqualityComparer<T3>.Default.Equals(P3, other.P3);
    }
    public static bool operator==(R3? left, R3? right)
        => (object)left == right || (left?.Equals(right) ?? false);
    public static bool operator!=(R3? left, R3? right)
        => !(left == right);
    public override int GetHashCode()
    {
        return Combine(base.GetHashCode(),
            EqualityComparer<T3>.Default.GetHashCode(P3));
    }
}

```

Copy and Clone members

A record type contains two copying members:

- A constructor taking a single argument of the record type. It is referred to as a "copy constructor".
- A synthesized public parameterless instance "clone" method with a compiler-reserved name

The purpose of the copy constructor is to copy the state from the parameter to the new instance being created. This constructor doesn't run any instance field/property initializers present in the record declaration. If the constructor is not explicitly declared, a constructor will be synthesized by the compiler. If the record is sealed, the constructor will be private, otherwise it will be protected. An explicitly declared copy constructor must be either public or protected, unless the record is sealed. The first thing the constructor must do, is to call a copy constructor of the base, or a parameter-less object constructor if the record inherits from object. An error is reported if a user-defined copy constructor uses an implicit or explicit constructor initializer that doesn't fulfill this requirement. After a base copy constructor is invoked, a synthesized copy constructor copies values for all instance fields implicitly or explicitly declared within the record type. The sole presence of a copy constructor, whether explicit or implicit, doesn't prevent an automatic addition of a default instance constructor.

If a virtual "clone" method is present in the base record, the synthesized "clone" method overrides it and the return type of the method is the current containing type if the "covariant returns" feature is supported and the override return type otherwise. An error is produced if the base record clone method is sealed. If a virtual "clone" method is not present in the base record, the return type of the clone method is the containing type and the method is virtual, unless the record is sealed or abstract. If the containing record is abstract, the synthesized clone method is also abstract. If the "clone" method is not abstract, it returns the result of a call to a copy constructor.

Printing members: PrintMembers and ToString methods

If the record is derived from `object`, the record includes a synthesized method equivalent to a method declared as follows:

```
bool PrintMembers(System.Text.StringBuilder builder);
```

The method is `private` if the record type is `sealed`. Otherwise, the method is `virtual` and `protected`.

The method:

1. calls the method `System.Runtime.CompilerServices.RuntimeHelpers.EnsureSufficientExecutionStack()` if the method is present and the record has printable members.
2. for each of the record's printable members (non-static public field and readable property members), appends that member's name followed by " = " followed by the member's value separated with ";",
3. return true if the record has printable members.

For a member that has a value type, we will convert its value to a string representation using the most efficient method available to the target platform. At present that means calling `ToString` before passing to `StringBuilder.Append`.

If the record type is derived from a base record `Base`, the record includes a synthesized override equivalent to a method declared as follows:

```
protected override bool PrintMembers(StringBuilder builder);
```

If the record has no printable members, the method calls the base `PrintMembers` method with one argument (its `builder` parameter) and returns the result.

Otherwise, the method:

1. calls the base `PrintMembers` method with one argument (its `builder` parameter),
2. if the `PrintMembers` method returned true, append ", " to the builder,
3. for each of the record's printable members, appends that member's name followed by " = " followed by the member's value: `this.member` (or `this.member.ToString()` for value types), separated with ", ",
4. return true.

The `PrintMembers` method can be declared explicitly. It is an error if the explicit declaration does not match the expected signature or accessibility, or if the explicit declaration doesn't allow overriding it in a derived type and the record type is not `sealed`.

The record includes a synthesized method equivalent to a method declared as follows:

```
public override string ToString();
```

The method can be declared explicitly. It is an error if the explicit declaration does not match the expected signature or accessibility, or if the explicit declaration doesn't allow overriding it in a derived type and the record type is not `sealed`. It is an error if either synthesized, or explicitly declared method doesn't override `object.ToString()` (for example, due to shadowing in intermediate base types, etc.).

The synthesized method:

1. creates a `StringBuilder` instance,
2. appends the record name to the builder, followed by " { ",
3. invokes the record's `PrintMembers` method giving it the builder, followed by " " if it returned true,
4. appends "}",
5. returns the builder's contents with `builder.ToString()`.

For example, consider the following record types:

```
record R1(T1 P1);  
record R2(T1 P1, T2 P2, T3 P3) : R1(P1);
```

For those record types, the synthesized printing members would be something like:

```

class R1 : IEquatable<R1>
{
    public T1 P1 { get; init; }

    protected virtual bool PrintMembers(StringBuilder builder)
    {
        builder.Append(nameof(P1));
        builder.Append(" = ");
        builder.Append(this.P1); // or builder.Append(this.P1.ToString()); if P1 has a value type

        return true;
    }

    public override string ToString()
    {
        var builder = new StringBuilder();
        builder.Append(nameof(R1));
        builder.Append(" { ");

        if (PrintMembers(builder))
            builder.Append(" ");

        builder.Append("}");
        return builder.ToString();
    }
}

class R2 : R1, IEquatable<R2>
{
    public T2 P2 { get; init; }
    public T3 P3 { get; init; }

    protected override bool PrintMembers(StringBuilder builder)
    {
        if (base.PrintMembers(builder))
            builder.Append(", ");

        builder.Append(nameof(P2));
        builder.Append(" = ");
        builder.Append(this.P2); // or builder.Append(this.P2); if P2 has a value type

        builder.Append(", ");

        builder.Append(nameof(P3));
        builder.Append(" = ");
        builder.Append(this.P3); // or builder.Append(this.P3); if P3 has a value type

        return true;
    }

    public override string ToString()
    {
        var builder = new StringBuilder();
        builder.Append(nameof(R2));
        builder.Append(" { ");

        if (PrintMembers(builder))
            builder.Append(" ");

        builder.Append("}");
        return builder.ToString();
    }
}

```

Positional record members

In addition to the above members, records with a parameter list ("positional records") synthesize additional members with the same conditions as the members above.

Primary Constructor

A record type has a public constructor whose signature corresponds to the value parameters of the type declaration. This is called the primary constructor for the type, and causes the implicitly declared default class constructor, if present, to be suppressed. It is an error to have a primary constructor and a constructor with the same signature already present in the class.

At runtime the primary constructor

1. executes the instance initializers appearing in the class-body
2. invokes the base class constructor with the arguments provided in the `record_base` clause, if present

If a record has a primary constructor, any user-defined constructor, except "copy constructor" must have an explicit `this` constructor initializer.

Parameters of the primary constructor as well as members of the record are in scope within the `argument_list` of the `record_base` clause and within initializers of instance fields or properties. Instance members would be an error in these locations (similar to how instance members are in scope in regular constructor initializers today, but an error to use), but the parameters of the primary constructor would be in scope and useable and would shadow members. Static members would also be useable, similar to how base calls and initializers work in ordinary constructors today.

A warning is produced if a parameter of the primary constructor is not read.

Expression variables declared in the `argument_list` are in scope within the `argument_list`. The same shadowing rules as within an argument list of a regular constructor initializer apply.

Properties

For each record parameter of a record type declaration there is a corresponding public property member whose name and type are taken from the value parameter declaration.

For a record:

- A public `get` and `init` auto-property is created (see separate `init` accessor specification). An inherited `abstract` property with matching type is overridden. It is an error if the inherited property does not have `public` overridable `get` and `init` accessors. It is an error if the inherited property is hidden. The auto-property is initialized to the value of the corresponding primary constructor parameter. Attributes can be applied to the synthesized auto-property and its backing field by using `property:` or `field:` targets for attributes syntactically applied to the corresponding record parameter.

Deconstruct

A positional record with at least one parameter synthesizes a public void-returning instance method called `Deconstruct` with an out parameter declaration for each parameter of the primary constructor declaration. Each parameter of the `Deconstruct` method has the same type as the corresponding parameter of the primary constructor declaration. The body of the method assigns each parameter of the `Deconstruct` method to the value from an instance member access to a member of the same name. The method can be declared explicitly. It is an error if the explicit declaration does not match the expected signature or accessibility, or is static.

`with` expression

A `with` expression is a new expression using the following syntax.

```
with_expression
: switch_expression
| switch_expression 'with' '{' member_initializer_list? '}'
;

member_initializer_list
: member_initializer (',' member_initializer)*
;

member_initializer
: identifier '=' expression
;
```

A `with` expression is not permitted as a statement.

A `with` expression allows for "non-destructive mutation", designed to produce a copy of the receiver expression with modifications in assignments in the `member_initializer_list`.

A valid `with` expression has a receiver with a non-void type. The receiver type must be a record.

On the right hand side of the `with` expression is a `member_initializer_list` with a sequence of assignments to *identifier*, which must be an accessible instance field or property of the receiver's type.

First, receiver's "clone" method (specified above) is invoked and its result is converted to the receiver's type.

Then, each `member_initializer` is processed the same way as an assignment to a field or property access of the result of the conversion. Assignments are processed in lexical order.

Top-level statements

12/28/2021 • 4 minutes to read • [Edit Online](#)

Summary

Allow a sequence of *statements* to occur right before the *namespace_member_declarations* of a *compilation_unit* (i.e. source file).

The semantics are that if such a sequence of *statements* is present, the following type declaration, modulo the actual type name and the method name, would be emitted:

```
static class Program
{
    static async Task Main(string[] args)
    {
        // statements
    }
}
```

See also <https://github.com/dotnet/csharplang/issues/3117>.

Motivation

There's a certain amount of boilerplate surrounding even the simplest of programs, because of the need for an explicit `Main` method. This seems to get in the way of language learning and program clarity. The primary goal of the feature therefore is to allow C# programs without unnecessary boilerplate around them, for the sake of learners and the clarity of code.

Detailed design

Syntax

The only additional syntax is allowing a sequence of *statements* in a compilation unit, just before the *namespace_member_declarations*:

```
compilation_unit
: extern_alias_directive* using_directive* global_attributes? statement* namespace_member_declaration*
;
```

Only one *compilation_unit* is allowed to have *statements*.

Example:

```

if (args.Length == 0
    || !int.TryParse(args[0], out int n)
    || n < 0) return;
Console.WriteLine(Fib(n).curr);

(int curr, int prev) Fib(int i)
{
    if (i == 0) return (1, 0);
    var (curr, prev) = Fib(i - 1);
    return (curr + prev, curr);
}

```

Semantics

If any top-level statements are present in any compilation unit of the program, the meaning is as if they were combined in the block body of a `Main` method of a `Program` class in the global namespace, as follows:

```

static class Program
{
    static async Task Main(string[] args)
    {
        // statements
    }
}

```

Note that the names "Program" and "Main" are used only for illustrations purposes, actual names used by compiler are implementation dependent and neither the type, nor the method can be referenced by name from source code.

The method is designated as the entry point of the program. Explicitly declared methods that by convention could be considered as an entry point candidates are ignored. A warning is reported when that happens. It is an error to specify `-main:<type>` compiler switch when there are top-level statements.

The entry point method always has one formal parameter, `string[] args`. The execution environment creates and passes a `string[]` argument containing the command-line arguments that were specified when the application was started. The `string[]` argument is never null, but it may have a length of zero if no command-line arguments were specified. The 'args' parameter is in scope within top-level statements and is not in scope outside of them. Regular name conflict/shadowing rules apply.

Async operations are allowed in top-level statements to the degree they are allowed in statements within a regular async entry point method. However, they are not required, if `await` expressions and other async operations are omitted, no warning is produced.

The signature of the generated entry point method is determined based on operations used by the top level statements as follows:

ASYNC-OPERATIONS\RETURN-WITH-EXPRESSION	PRESENT	ABSENT
Present	<code>static Task<int> Main(string[] args)</code>	<code>static Task Main(string[] args)</code>
Absent	<code>static int Main(string[] args)</code>	<code>static void Main(string[] args)</code>

The example above would yield the following `$Main` method declaration:

```

static class $Program
{
    static void $Main(string[] args)
    {
        if (args.Length == 0
            || !int.TryParse(args[0], out int n)
            || n < 0) return;
        Console.WriteLine(Fib(n).curr);

        (int curr, int prev) Fib(int i)
        {
            if (i == 0) return (1, 0);
            var (curr, prev) = Fib(i - 1);
            return (curr + prev, curr);
        }
    }
}

```

At the same time an example like this:

```

await System.Threading.Tasks.Task.Delay(1000);
System.Console.WriteLine("Hi!");

```

would yield:

```

static class $Program
{
    static async Task $Main(string[] args)
    {
        await System.Threading.Tasks.Task.Delay(1000);
        System.Console.WriteLine("Hi!");
    }
}

```

An example like this:

```

await System.Threading.Tasks.Task.Delay(1000);
System.Console.WriteLine("Hi!");
return 0;

```

would yield:

```

static class $Program
{
    static async Task<int> $Main(string[] args)
    {
        await System.Threading.Tasks.Task.Delay(1000);
        System.Console.WriteLine("Hi!");
        return 0;
    }
}

```

And an example like this:

```

System.Console.WriteLine("Hi!");
return 2;

```

would yield:

```
static class $Program
{
    static int $Main(string[] args)
    {
        System.Console.WriteLine("Hi!");
        return 2;
    }
}
```

Scope of top-level local variables and local functions

Even though top-level local variables and functions are "wrapped" into the generated entry point method, they should still be in scope throughout the program in every compilation unit. For the purpose of simple-name evaluation, once the global namespace is reached:

- First, an attempt is made to evaluate the name within the generated entry point method and only if this attempt fails
- The "regular" evaluation within the global namespace declaration is performed.

This could lead to name shadowing of namespaces and types declared within the global namespace as well as to shadowing of imported names.

If the simple name evaluation occurs outside of the top-level statements and the evaluation yields a top-level local variable or function, that should lead to an error.

In this way we protect our future ability to better address "Top-level functions" (scenario 2 in <https://github.com/dotnet/csharplang/issues/3117>), and are able to give useful diagnostics to users who mistakenly believe them to be supported.

Nullable Reference Types Specification

12/28/2021 • 18 minutes to read • [Edit Online](#)

This is a work in progress - several parts are missing or incomplete.

This feature adds two new kinds of nullable types (nullable reference types and nullable generic types) to the existing nullable value types, and introduces a static flow analysis for purpose of null-safety.

Syntax

Nullable reference types and nullable type parameters

Nullable reference types and nullable type parameters have the same syntax `T?` as the short form of nullable value types, but do not have a corresponding long form.

For the purposes of the specification, the current `nullable_type` production is renamed to `nullable_value_type`, and `nullable_reference_type` and `nullable_type_parameter` productions are added:

```
type
    : value_type
    | reference_type
    | nullable_type_parameter
    | type_parameter
    | type_unsafe
    ;

reference_type
    : ...
    | nullable_reference_type
    ;

nullable_reference_type
    : non_nullable_reference_type '?'
    ;

non_nullable_reference_type
    : reference_type
    ;

nullable_type_parameter
    : non_nullable_non_value_type_parameter '?'
    ;

non_nullable_non_value_type_parameter
    : type_parameter
    ;
```

The `non_nullable_reference_type` in a `nullable_reference_type` must be a nonnullable reference type (class, interface, delegate or array).

The `non_nullable_non_value_type_parameter` in `nullable_type_parameter` must be a type parameter that isn't constrained to be a value type.

Nullable reference types and nullable type parameters cannot occur in the following positions:

- as a base class or interface
- as the receiver of a `member_access`

- as the `type` in an `object_creation_expression`
- as the `delegate_type` in a `delegate_creation_expression`
- as the `type` in an `is_expression`, a `catch_clause` or a `type_pattern`
- as the `interface` in a fully qualified interface member name

A warning is given on a `nullable_reference_type` and `nullable_type_parameter` in a *disabled* nullable annotation context.

`class` **and** `class?` **constraint**

The `class` constraint has a nullable counterpart `class?`:

```
primary_constraint
: ...
| 'class' '?'
;
```

A type parameter constrained with `class` (in an *enabled* annotation context) must be instantiated with a nonnullable reference type.

A type parameter constrained with `class?` (or `class` in a *disabled* annotation context) may either be instantiated with a nullable or nonnullable reference type.

A warning is given on a `class?` constraint in a *disabled* annotation context.

`notnull` **constraint**

A type parameter constrained with `notnull` may not be a nullable type (nullable value type, nullable reference type or nullable type parameter).

```
primary_constraint
: ...
| 'notnull'
;
```

`default` **constraint**

The `default` constraint can be used on a method override or explicit implementation to disambiguate `T?` meaning "nullable type parameter" from "nullable value type" (`Nullable<T>`). Lacking the `default` constraint a `T?` syntax in an override or explicit implementation will be interpreted as `Nullable<T>`.

See <https://github.com/dotnet/csharplang/blob/master/proposals/csharp-9.0/unconstrained-type-parameter-annotations.md#default-constraint>

The null-forgiving operator

The post-fix `!` operator is called the null-forgiving operator. It can be applied on a *primary_expression* or within a *null_conditional_expression*.

```

primary_expression
: ...
| null_forgiving_expression
;

null_forgiving_expression
: primary_expression '!'
;

null_conditional_expression
: primary_expression null_conditional_operations_no_suppression suppression?
;

null_conditional_operations_no_suppression
: null_conditional_operations? '?' '.' identifier type_argument_list?
| null_conditional_operations? '?' '[' argument_list ']'
| null_conditional_operations '.' identifier type_argument_list?
| null_conditional_operations '[' argument_list ']'
| null_conditional_operations '(' argument_list? ')'
;

null_conditional_operations
: null_conditional_operations_no_suppression suppression?
;

suppression
: '!'
;

```

For example:

```

var v = expr!;
expr!.M();
_ = a?.b!.c;

```

The postfix `!` operator has no runtime effect - it evaluates to the result of the underlying expression. Its only role is to change the null state of the expression to "not null", and to limit warnings given on its use.

Nullable compiler directives

`#nullable` directives control the nullable annotation and warning contexts.

```

pp_directive
: ...
| pp_nullable
;

pp_nullable
: whitespace? '#' whitespace? 'nullable' whitespace nullable_action (whitespace nullable_target)?
pp_new_line
;

nullable_action
: 'disable'
| 'enable'
| 'restore'
;

nullable_target
: 'warnings'
| 'annotations'
;

```

`#pragma warning` directives are expanded to allow changing the nullable warning context:

```
pragma_warning_body
: ...
| 'warning' whitespace warning_action whitespace 'nullable'
;
```

For example:

```
#pragma warning disable nullable
```

Nullable contexts

Every line of source code has a *nullable annotation context* and a *nullable warning context*. These control whether nullable annotations have effect, and whether nullability warnings are given. The annotation context of a given line is either *disabled* or *enabled*. The warning context of a given line is either *disabled* or *enabled*.

Both contexts can be specified at the project level (outside of C# source code), or anywhere within a source file via `#nullable` pre-processor directives. If no project level settings are provided the default is for both contexts to be *disabled*.

The `#nullable` directive controls the annotation and warning contexts within the source text, and take precedence over the project-level settings.

A directive sets the context(s) it controls for subsequent lines of code, until another directive overrides it, or until the end of the source file.

The effect of the directives is as follows:

- `#nullable disable` : Sets the nullable annotation and warning contexts to *disabled*
- `#nullable enable` : Sets the nullable annotation and warning contexts to *enabled*
- `#nullable restore` : Restores the nullable annotation and warning contexts to project settings
- `#nullable disable annotations` : Sets the nullable annotation context to *disabled*
- `#nullable enable annotations` : Sets the nullable annotation context to *enabled*
- `#nullable restore annotations` : Restores the nullable annotation context to project settings
- `#nullable disable warnings` : Sets the nullable warning context to *disabled*
- `#nullable enable warnings` : Sets the nullable warning context to *enabled*
- `#nullable restore warnings` : Restores the nullable warning context to project settings

Nullability of types

A given type can have one of three nullabilities: *oblivious*, *nonnullable*, and *nullable*.

Nonnullable types may cause warnings if a potential `null` value is assigned to them. *Oblivious* and *nullable* types, however, are "null-assignable" and can have `null` values assigned to them without warnings.

Values of *oblivious* and *nonnullable* types can be dereferenced or assigned without warnings. Values of *nullable* types, however, are "null-yielding" and may cause warnings when dereferenced or assigned without proper null checking.

The *default null state* of a null-yielding type is "maybe null" or "maybe default". The default null state of a non-null-yielding type is "not null".

The kind of type and the nullable annotation context it occurs in determine its nullability:

- A nonnullable value type `S` is always *nonnullable*
- A nullable value type `S?` is always *nullable*
- An unannotated reference type `C` in a *disabled* annotation context is *oblivious*
- An unannotated reference type `C` in an *enabled* annotation context is *nonnullable*
- A nullable reference type `C?` is *nullable* (but a warning may be yielded in a *disabled* annotation context)

Type parameters additionally take their constraints into account:

- A type parameter `T` where all constraints (if any) are either nullable types or the `class?` constraint is *nullable*
- A type parameter `T` where at least one constraint is either *oblivious* or *nonnullable* or one of the `struct` or `class` or `notnull` constraints is
 - *oblivious* in a *disabled* annotation context
 - *nonnullable* in an *enabled* annotation context
- A nullable type parameter `T?` is *nullable*, but a warning is yielded in a *disabled* annotation context if `T` isn't a value type

Oblivious vs nonnullable

A `type` is deemed to occur in a given annotation context when the last token of the type is within that context.

Whether a given reference type `C` in source code is interpreted as oblivious or nonnullable depends on the annotation context of that source code. But once established, it is considered part of that type, and "travels with it" e.g. during substitution of generic type arguments. It is as if there is an annotation like `?` on the type, but invisible.

Constraints

Nullable reference types can be used as generic constraints.

`class?` is a new constraint denoting "possibly nullable reference type", whereas `class` in an *enabled* annotation context denotes "nonnullable reference type".

`default` is a new constraint denoting a type parameter that isn't known to be a reference or value type. It can only be used on overridden and explicitly implemented methods. With this constraint, `T?` means a nullable type parameter, as opposed to being a shorthand for `Nullable<T>`.

`notnull` is a new constraint denoting a type parameter that is nonnullable.

The nullability of a type argument or of a constraint does not impact whether the type satisfies the constraint, except where that is already the case today (nullable value types do not satisfy the `struct` constraint). However, if the type argument does not satisfy the nullability requirements of the constraint, a warning may be given.

Null state and null tracking

Every expression in a given source location has a *null state*, which indicated whether it is believed to potentially evaluate to null. The null state is either "not null", "maybe null", or "maybe default". The null state is used to determine whether a warning should be given about null-unsafe conversions and dereferences.

The distinction between "maybe null" and "maybe default" is subtle and applies to type parameters. The distinction is that a type parameter `T` which has the state "maybe null" means the value is in the domain of legal values for `T` however that legal value may include `null`. Whereas a "maybe default" means that the value may be outside the legal domain of values for `T`.

Example:

```
// The value `t` here has the state "maybe null". It's possible for `T` to be instantiated
// with `string?` in which case `null` would be within the domain of legal values here. The
// assumption though is the value provided here is within the legal values of `T`. Hence
// if `T` is `string` then `null` will not be a value, just as we assume that `null` is not
// provided for a normal `string` parameter
void M<T>(T t)
{
    // There is no guarantee that default(T) is within the legal values for T hence the
    // state *must* be "maybe-default" and hence `local` must be `T?`
    T? local = default(T);
}
```

Null tracking for variables

For certain expressions denoting variables, fields or properties, the null state is tracked between occurrences, based on assignments to them, tests performed on them and the control flow between them. This is similar to how definite assignment is tracked for variables. The tracked expressions are the ones of the following form:

```
tracked_expression
: simple_name
| this
| base
| tracked_expression '.' identifier
;
```

Where the identifiers denote fields or properties.

The null state for tracked variables is "not null" in unreachable code. This follows other decisions around unreachable code like considering all locals to be definitely assigned.

Describe null state transitions similar to definite assignment

Null state for expressions

The null state of an expression is derived from its form and type, and from the null state of variables involved in it.

Literals

The null state of a `null` literal depends on the target type of the expression. If the target type is a type parameter constrained to a reference type then it's "maybe default". Otherwise it is "maybe null".

The null state of a `default` literal depends on the target type of the `default` literal. A `default` literal with target type `T` has the same null state as the `default(T)` expression.

The null state of any other literal is "not null".

Simple names

If a `simple_name` is not classified as a value, its null state is "not null". Otherwise it is a tracked expression, and its null state is its tracked null state at this source location.

Member access

If a `member_access` is not classified as a value, its null state is "not null". Otherwise, if it is a tracked expression, its null state is its tracked null state at this source location. Otherwise its null state is the default null state of its type.

```

var person = new Person();

// The receiver is a tracked expression hence the member_access of the property
// is tracked as well
if (person.FirstName is not null)
{
    Use(person.FirstName);
}

// The return of an invocation is not a tracked expression hence the member_access
// of the return is also not tracked
if (GetAnonymous().FirstName is not null)
{
    // Warning: Cannot convert null literal to non-nullable reference type.
    Use(GetAnonymous().FirstName);
}

void Use(string s)
{
    // ...
}

public class Person
{
    public string? FirstName { get; set; }
    public string? LastName { get; set; }

    private static Person s_anonymous = new Person();
    public static Person GetAnonymous() => s_anonymous;
}

```

Invocation expressions

If an `invocation_expression` invokes a member that is declared with one or more attributes for special null behavior, the null state is determined by those attributes. Otherwise the null state of the expression is the default null state of its type.

The null state of an `invocation_expression` is not tracked by the compiler.

```

// The result of an invocation_expression is not tracked
if (GetText() is not null)
{
    // Warning: Converting null literal or possible null value to non-nullable type.
    string s = GetText();
    // Warning: Dereference of a possibly null reference.
    Use(s);
}

// Nullable friendly pattern
if (GetText() is string s)
{
    Use(s);
}

string? GetText() => ...
Use(string s) { }

```

Element access

If an `element_access` invokes an indexer that is declared with one or more attributes for special null behavior, the null state is determined by those attributes. Otherwise the null state of the expression is the default null state of its type.

```

object?[] array = ...;
if (array[0] != null)
{
    // Warning: Converting null literal or possible null value to non-nullable type.
    object o = array[0];
    // Warning: Dereference of a possibly null reference.
    Console.WriteLine(o.ToString());
}

// Nullable friendly pattern
if (array[0] is {} o)
{
    Console.WriteLine(o.ToString());
}

```

Base access

If `B` denotes the base type of the enclosing type, `base.I` has the same null state as `((B)this).I` and `base[E]` has the same null state as `((B)this)[E]`.

Default expressions

`default(T)` has the null state based on the properties of the type `T`:

- If the type is a *nonnullable* type then it has the null state "not null"
- Else if the type is a type parameter then it has the null state "maybe default"
- Else it has the null state "maybe null"

Null-conditional expressions ?.

A `null_conditional_expression` has the null state based on the expression type. Note that this refers to the type of the `null_conditional_expression`, not the original type of the member being invoked:

- If the type is a *nullable* value type then it has the null state "maybe null"
- Else if the type is a *nullable* type parameter then it has the null state "maybe default"
- Else it has the null state "maybe null"

Cast expressions

If a cast expression `(T)E` invokes a user-defined conversion, then the null state of the expression is the default null state for the type of the user-defined conversion. Otherwise:

- If `T` is a *nonnullable* value type then `T` has the null state "not null"
- Else if `T` is a *nullable* value type then `T` has the null state "maybe null"
- Else if `T` is a *nullable* type in the form `U?` where `U` is a type parameter then `T` has the null state "maybe default"
- Else if `T` is a *nullable* type, and `E` has null state "maybe null" or "maybe default", then `T` has the null state "maybe null"
- Else if `T` is a type parameter, and `E` has null state "maybe null" or "maybe default", then `T` has the null state "maybe default"
- Else `T` has the same null state as `E`

Unary and binary operators

If a unary or binary operator invokes an user-defined operator then the null state of the expression is the default null state for the type of the user-defined operator. Otherwise it is the null state of the expression.

Something special to do for binary `+` over strings and delegates?

Await expressions

The null state of `await E` is the default null state of its type.

The `as` operator

The null state of an `E as T` expression depends first on properties of the type `T`. If the type of `T` is *nonnullable* then the null state is "not null". Otherwise the null state depends on the conversion from the type of `E` to type `T`:

- If the conversion is an identity, boxing, implicit reference, or implicit nullable conversion, then the null state is the null state of `E`
- Else if `T` is a type parameter then it has the null state "maybe default"
- Else it has the null state "maybe null"

The null-coalescing operator

The null state of `E1 ?? E2` is the null state of `E2`

The conditional operator

The null state of `E1 ? E2 : E3` is based on the null state of `E2` and `E3`:

- If both are "not null" then the null state is "not null"
- Else if either is "maybe default" then the null state is "maybe default"
- Else the null state is "not null"

Query expressions

The null state of a query expression is the default null state of its type.

Additional work needed here

Assignment operators

`E1 = E2` and `E1 op= E2` have the same null state as `E2` after any implicit conversions have been applied.

Expressions that propagate null state

`(E)`, `checked(E)` and `unchecked(E)` all have the same null state as `E`.

Expressions that are never null

The null state of the following expression forms is always "not null":

- `this` access
- interpolated strings
- `new` expressions (object, delegate, anonymous object and array creation expressions)
- `typeof` expressions
- `nameof` expressions
- anonymous functions (anonymous methods and lambda expressions)
- null-forgiving expressions
- `is` expressions

Nested functions

Nested functions (lambdas and local functions) are treated like methods, except in regards to their captured variables. The initial state of a captured variable inside a lambda or local function is the intersection of the nullable state of the variable at all the "uses" of that nested function or lambda. A use of a local function is either a call to that function, or where it is converted to a delegate. A use of a lambda is the point at which it is defined in source.

Type inference

nullable implicitly typed local variables

`var` infers an annotated type for reference types, and type parameters that aren't constrained to be a value type. For instance:

- in `var s = ""`; the `var` is inferred as `string?`.
- in `var t = new T()`; with an unconstrained `T` the `var` is inferred as `T?`.

Generic type inference

Generic type inference is enhanced to help decide whether inferred reference types should be nullable or not. This is a best effort. It may yield warnings regarding nullability constraints, and may lead to nullable warnings when the inferred types of the selected overload are applied to the arguments.

The first phase

Nullable reference types flow into the bounds from the initial expressions, as described below. In addition, two new kinds of bounds, namely `null` and `default` are introduced. Their purpose is to carry through occurrences of `null` or `default` in the input expressions, which may cause an inferred type to be nullable, even when it otherwise wouldn't.

The determination of what bounds to add in the first phase are enhanced as follows:

If an argument `Ei` has a reference type, the type `U` used for inference depends on the null state of `Ei` as well as its declared type:

- If the declared type is a nonnullable reference type `U0` or a nullable reference type `U0?` then
 - if the null state of `Ei` is "not null" then `U` is `U0`
 - if the null state of `Ei` is "maybe null" then `U` is `U0?`
- Otherwise if `Ei` has a declared type, `U` is that type
- Otherwise if `Ei` is `null` then `U` is the special bound `null`
- Otherwise if `Ei` is `default` then `U` is the special bound `default`
- Otherwise no inference is made.

Exact, upper-bound and lower-bound inferences

In inferences *from* the type `U` *to* the type `V`, if `V` is a nullable reference type `V0?`, then `V0` is used instead of `V` in the following clauses.

- If `V` is one of the unfixed type variables, `U` is added as an exact, upper or lower bound as before
- Otherwise, if `U` is `null` or `default`, no inference is made
- Otherwise, if `U` is a nullable reference type `U0?`, then `U0` is used instead of `U` in the subsequent clauses.

The essence is that nullability that pertains directly to one of the unfixed type variables is preserved into its bounds. For the inferences that recurse further into the source and target types, on the other hand, nullability is ignored. It may or may not match, but if it doesn't, a warning will be issued later if the overload is chosen and applied.

Fixing

The spec currently does not do a good job of describing what happens when multiple bounds are identity convertible to each other, but are different. This may happen between `object` and `dynamic`, between tuple types that differ only in element names, between types constructed thereof and now also between `C` and `C?` for reference types.

In addition we need to propagate "nullness" from the input expressions to the result type.

To handle these we add more phases to fixing, which is now:

1. Gather all the types in all the bounds as candidates, removing `?` from all that are nullable reference types

2. Eliminate candidates based on requirements of exact, lower and upper bounds (keeping `null` and `default` bounds)
3. Eliminate candidates that do not have an implicit conversion to all the other candidates
4. If the remaining candidates do not all have identity conversions to one another, then type inference fails
5. *Merge* the remaining candidates as described below
6. If the resulting candidate is a reference type and *all* of the exact bounds or *any* of the lower bounds are nullable reference types, `null` or `default`, then `?` is added to the resulting candidate, making it a nullable reference type.

Merging is described between two candidate types. It is transitive and commutative, so the candidates can be merged in any order with the same ultimate result. It is undefined if the two candidate types are not identity convertible to each other.

The *Merge* function takes two candidate types and a direction (+ or -):

- $\text{Merge}(T, T, d) = T$
- $\text{Merge}(S, T?, +) = \text{Merge}(S?, T, +) = \text{Merge}(S, T, +)?$
- $\text{Merge}(S, T?, -) = \text{Merge}(S?, T, -) = \text{Merge}(S, T, -)$
- $\text{Merge}(C\langle S_1, \dots, S_n \rangle, C\langle T_1, \dots, T_n \rangle, +) = C\langle \text{Merge}(S_1, T_1, d_1), \dots, \text{Merge}(S_n, T_n, d_n) \rangle$, where
 - $d_i = +$ if the i 'th type parameter of $C\langle \dots \rangle$ is covariant
 - $d_i = -$ if the i 'th type parameter of $C\langle \dots \rangle$ is contra- or invariant
- $\text{Merge}(C\langle S_1, \dots, S_n \rangle, C\langle T_1, \dots, T_n \rangle, -) = C\langle \text{Merge}(S_1, T_1, d_1), \dots, \text{Merge}(S_n, T_n, d_n) \rangle$, where
 - $d_i = -$ if the i 'th type parameter of $C\langle \dots \rangle$ is covariant
 - $d_i = +$ if the i 'th type parameter of $C\langle \dots \rangle$ is contra- or invariant
- $\text{Merge}(S_1\ s_1, \dots, S_n\ s_n, (T_1\ t_1, \dots, T_n\ t_n), d) = (\text{Merge}(S_1, T_1, d)_{n_1}, \dots, \text{Merge}(S_n, T_n, d)_{n_n})$, where
 - n_i is absent if s_i and t_i differ, or if both are absent
 - n_i is s_i if s_i and t_i are the same
- $\text{Merge}(\text{object}, \text{dynamic}) = \text{Merge}(\text{dynamic}, \text{object}) = \text{dynamic}$

Pattern-matching changes for C# 9.0

12/28/2021 • 11 minutes to read • [Edit Online](#)

We are considering a small handful of enhancements to pattern-matching for C# 9.0 that have natural synergy and work well to address a number of common programming problems:

- <https://github.com/dotnet/csharpplang/issues/2925> Type patterns
- <https://github.com/dotnet/csharpplang/issues/1350> Parenthesized patterns to enforce or emphasize precedence of the new combinators
- <https://github.com/dotnet/csharpplang/issues/1350> Conjunctive `and` patterns that require both of two different patterns to match;
- <https://github.com/dotnet/csharpplang/issues/1350> Disjunctive `or` patterns that require either of two different patterns to match;
- <https://github.com/dotnet/csharpplang/issues/1350> Negated `not` patterns that require a given pattern *not* to match; and
- <https://github.com/dotnet/csharpplang/issues/812> Relational patterns that require the input value to be less than, less than or equal to, etc a given constant.

Parenthesized Patterns

Parenthesized patterns permit the programmer to put parentheses around any pattern. This is not so useful with the existing patterns in C# 8.0, however the new pattern combinators introduce a precedence that the programmer may want to override.

```
primary_pattern
    : parenthesized_pattern
    | // all of the existing forms
    ;
parenthesized_pattern
    : '(' pattern ')'
```

Type Patterns

We permit a type as a pattern:

```
primary_pattern
    : type-pattern
    | // all of the existing forms
    ;
type_pattern
    : type
```

This retcons the existing *is-type-expression* to be an *is-pattern-expression* in which the pattern is a *type-pattern*, though we would not change the syntax tree produced by the compiler.

One subtle implementation issue is that this grammar is ambiguous. A string such as `a.b` can be parsed either as a qualified name (in a type context) or a dotted expression (in an expression context). The compiler is already capable of treating a qualified name the same as a dotted expression in order to handle something like

`e is Color.Red`. The compiler's semantic analysis would be further extended to be capable of binding a (syntactic) constant pattern (e.g. a dotted expression) as a type in order to treat it as a bound type pattern in order to support this construct.

After this change, you would be able to write

```
void M(object o1, object o2)
{
    var t = (o1, o2);
    if (t is (int, string)) {} // test if o1 is an int and o2 is a string
    switch (o1) {
        case int: break; // test if o1 is an int
        case System.String: break; // test if o1 is a string
    }
}
```

Relational Patterns

Relational patterns permit the programmer to express that an input value must satisfy a relational constraint when compared to a constant value:

```
public static LifeStage LifeStageAtAge(int age) => age switch
{
    < 0 => LifeStage.Prenatal,
    < 2 => LifeStage.Infant,
    < 4 => LifeStage.Toddler,
    < 6 => LifeStage.EarlyChild,
    < 12 => LifeStage.MiddleChild,
    < 20 => LifeStage.Adolescent,
    < 40 => LifeStage.EarlyAdult,
    < 65 => LifeStage.MiddleAdult,
    _ => LifeStage.LateAdult,
};
```

Relational patterns support the relational operators `<`, `<=`, `>`, and `>=` on all of the built-in types that support such binary relational operators with two operands of the same type in an expression. Specifically, we support all of these relational patterns for `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `long`, `ulong`, `char`, `float`, `double`, `decimal`, `nint`, and `nuint`.

```
primary_pattern
    : relational_pattern
    ;
relational_pattern
    : '<' relational_expression
    | '<=' relational_expression
    | '>' relational_expression
    | '>=' relational_expression
    ;
```

The expression is required to evaluate to a constant value. It is an error if that constant value is `double.NaN` or `float.NaN`. It is an error if the expression is a null constant.

When the input is a type for which a suitable built-in binary relational operator is defined that is applicable with the input as its left operand and the given constant as its right operand, the evaluation of that operator is taken as the meaning of the relational pattern. Otherwise we convert the input to the type of the expression using an explicit nullable or unboxing conversion. It is a compile-time error if no such conversion exists. The pattern is considered not to match if the conversion fails. If the conversion succeeds then the result of the pattern-

matching operation is the result of evaluating the expression `e OP v` where `e` is the converted input, `OP` is the relational operator, and `v` is the constant expression.

Pattern Combinators

Pattern *combinators* permit matching both of two different patterns using `and` (this can be extended to any number of patterns by the repeated use of `and`), either of two different patterns using `or` (ditto), or the *negation* of a pattern using `not`.

A common use of a combinator will be the idiom

```
if (e is not null) ...
```

More readable than the current idiom `e is object`, this pattern clearly expresses that one is checking for a non-null value.

The `and` and `or` combinators will be useful for testing ranges of values

```
bool IsLetter(char c) => c is >= 'a' and <= 'z' or >= 'A' and <= 'Z';
```

This example illustrates that `and` will have a higher parsing priority (i.e. will bind more closely) than `or`. The programmer can use the *parenthesized pattern* to make the precedence explicit:

```
bool IsLetter(char c) => c is (>= 'a' and <= 'z') or (>= 'A' and <= 'Z');
```

Like all patterns, these combinators can be used in any context in which a pattern is expected, including nested patterns, the *is-pattern-expression*, the *switch-expression*, and the pattern of a switch statement's case label.

```
pattern
: disjunctive_pattern
;
disjunctive_pattern
: disjunctive_pattern 'or' conjunctive_pattern
| conjunctive_pattern
;
conjunctive_pattern
: conjunctive_pattern 'and' negated_pattern
| negated_pattern
;
negated_pattern
: 'not' negated_pattern
| primary_pattern
;
primary_pattern
: // all of the patterns forms previously defined
;
```

Change to 7.5.4.2 Grammar Ambiguities

Due to the introduction of the *type pattern*, it is possible for a generic type to appear before the token `=>`. We therefore add `=>` to the set of tokens listed in *7.5.4.2 Grammar Ambiguities* to permit disambiguation of the `<` that begins the type argument list. See also <https://github.com/dotnet/roslyn/issues/47614>.

Open Issues with Proposed Changes

Syntax for relational operators

Are `and`, `or`, and `not` some kind of contextual keyword? If so, is there a breaking change (e.g. compared to their use as a designator in a *declaration-pattern*).

Semantics (e.g. type) for relational operators

We expect to support all of the primitive types that can be compared in an expression using a relational operator. The meaning in simple cases is clear

```
bool IsValidPercentage(int x) => x is >= 0 and <= 100;
```

But when the input is not such a primitive type, what type do we attempt to convert it to?

```
bool IsValidPercentage(object x) => x is >= 0 and <= 100;
```

We have proposed that when the input type is already a comparable primitive, that is the type of the comparison. However, when the input is not a comparable primitive, we treat the relational as including an implicit type test to the type of the constant on the right-hand-side of the relational. If the programmer intends to support more than one input type, that must be done explicitly:

```
bool IsValidPercentage(object x) => x is
    >= 0 and <= 100 or    // integer tests
    >= 0F and <= 100F or // float tests
    >= 0D and <= 100D;    // double tests
```

Flowing type information from the left to the right of `and`

It has been suggested that when you write an `and` combinator, type information learned on the left about the top-level type could flow to the right. For example

```
bool isSmallByte(object o) => o is byte and < 100;
```

Here, the *input type* to the second pattern is narrowed by the *type narrowing* requirements of left of the `and`. We would define type narrowing semantics for all patterns as follows. The *narrowed type* of a pattern `P` is defined as follows:

1. If `P` is a type pattern, the *narrowed type* is the type of the type pattern's type.
2. If `P` is a declaration pattern, the *narrowed type* is the type of the declaration pattern's type.
3. If `P` is a recursive pattern that gives an explicit type, the *narrowed type* is that type.
4. If `P` is [matched via the rules for](#) `ITuple`, the *narrowed type* is the type `System.Runtime.CompilerServices.ITuple`.
5. If `P` is a constant pattern where the constant is not the null constant and where the expression has no *constant expression conversion* to the *input type*, the *narrowed type* is the type of the constant.
6. If `P` is a relational pattern where the constant expression has no *constant expression conversion* to the *input type*, the *narrowed type* is the type of the constant.
7. If `P` is an `or` pattern, the *narrowed type* is the common type of the *narrowed type* of the subpatterns if such a common type exists. For this purpose, the common type algorithm considers only identity, boxing, and implicit reference conversions, and it considers all subpatterns of a sequence of `or` patterns (ignoring parenthesized patterns).
8. If `P` is an `and` pattern, the *narrowed type* is the *narrowed type* of the right pattern. Moreover, the *narrowed type* of the left pattern is the *input type* of the right pattern.
9. Otherwise the *narrowed type* of `P` is `P`'s input type.

Variable definitions and definite assignment

The addition of `or` and `not` patterns creates some interesting new problems around pattern variables and definite assignment. Since variables can normally be declared at most once, it would seem any pattern variable declared on one side of an `or` pattern would not be definitely assigned when the pattern matches. Similarly, a variable declared inside a `not` pattern would not be expected to be definitely assigned when the pattern matches. The simplest way to address this is to forbid declaring pattern variables in these contexts. However, this may be too restrictive. There are other approaches to consider.

One scenario that is worth considering is this

```
if (e is not int i) return;
M(i); // is i definitely assigned here?
```

This does not work today because, for an *is-pattern-expression*, the pattern variables are considered *definitely assigned* only where the *is-pattern-expression* is true ("definitely assigned when true").

Supporting this would be simpler (from the programmer's perspective) than also adding support for a negated-condition `if` statement. Even if we add such support, programmers would wonder why the above snippet does not work. On the other hand, the same scenario in a `switch` makes less sense, as there is no corresponding point in the program where *definitely assigned when false* would be meaningful. Would we permit this in an *is-pattern-expression* but not in other contexts where patterns are permitted? That seems irregular.

Related to this is the problem of definite assignment in a *disjunctive-pattern*.

```
if (e is 0 or int i)
{
    M(i); // is i definitely assigned here?
}
```

We would only expect `i` to be definitely assigned when the input is not zero. But since we don't know whether the input is zero or not inside the block, `i` is not definitely assigned. However, what if we permit `i` to be declared in different mutually exclusive patterns?

```
if ((e1, e2) is (0, int i) or (int i, 0))
{
    M(i);
}
```

Here, the variable `i` is definitely assigned inside the block, and takes its value from the other element of the tuple when a zero element is found.

It has also been suggested to permit variables to be (multiply) defined in every case of a case block:

```
case (0, int x):
case (int x, 0):
    Console.WriteLine(x);
```

To make any of this work, we would have to carefully define where such multiple definitions are permitted and under what conditions such a variable is considered definitely assigned.

Should we elect to defer such work until later (which I advise), we could say in C# 9

- beneath a `not` or `or`, pattern variables may not be declared.

Then, we would have time to develop some experience that would provide insight into the possible value of

relaxing that later.

Diagnostics, subsumption, and exhaustiveness

These new pattern forms introduce many new opportunities for diagnosable programmer error. We will need to decide what kinds of errors we will diagnose, and how to do so. Here are some examples:

```
case >= 0 and <= 100D:
```

This case can never match (because the input cannot be both an `int` and a `double`). We already have an error when we detect a case that can never match, but its wording ("The switch case has already been handled by a previous case" and "The pattern has already been handled by a previous arm of the switch expression") may be misleading in new scenarios. We may have to modify the wording to just say that the pattern will never match the input.

```
case 1 and 2:
```

Similarly, this would be an error because a value cannot be both `1` and `2`.

```
case 1 or 2 or 3 or 1:
```

This case is possible to match, but the `or 1` at the end adds no meaning to the pattern. I suggest we should aim to produce an error whenever some conjunct or disjunct of a compound pattern does not either define a pattern variable or affect the set of matched values.

```
case < 2: break;  
case 0 or 1 or 2 or 3 or 4 or 5: break;
```

Here, `0 or 1 or` adds nothing to the second case, as those values would have been handled by the first case. This too deserves an error.

```
byte b = ...;  
int x = b switch { <100 => 0, 100 => 1, 101 => 2, >101 => 3 };
```

A switch expression such as this should be considered *exhaustive* (it handles all possible input values).

In C# 8.0, a switch expression with an input of type `byte` is only considered exhaustive if it contains a final arm whose pattern matches everything (a *discard-pattern* or *var-pattern*). Even a switch expression that has an arm for every distinct `byte` value is not considered exhaustive in C# 8. In order to properly handle exhaustiveness of relational patterns, we will have to handle this case too. This will technically be a breaking change, but no user is likely to notice.

Init Only Setters

12/28/2021 • 15 minutes to read • [Edit Online](#)

Summary

This proposal adds the concept of init only properties and indexers to C#. These properties and indexers can be set at the point of object creation but become effectively `get` only once object creation has completed. This allows for a much more flexible immutable model in C#.

Motivation

The underlying mechanisms for building immutable data in C# haven't changed since 1.0. They remain:

1. Declaring fields as `readonly`.
2. Declaring properties that contain only a `get` accessor.

These mechanisms are effective at allowing the construction of immutable data but they do so by adding cost to the boilerplate code of types and opting such types out of features like object and collection initializers. This means developers must choose between ease of use and immutability.

A simple immutable object like `Point` requires twice as much boiler plate code to support construction as it does to declare the type. The bigger the type the bigger the cost of this boiler plate:

```
struct Point
{
    public int X { get; }
    public int Y { get; }

    public Point(int x, int y)
    {
        this.X = x;
        this.Y = y;
    }
}
```

The `init` accessor makes immutable objects more flexible by allowing the caller to mutate the members during the act of construction. That means the object's immutable properties can participate in object initializers and thus removes the need for all constructor boilerplate in the type. The `Point` type is now simply:

```
struct Point
{
    public int X { get; init; }
    public int Y { get; init; }
}
```

The consumer can then use object initializers to create the object

```
var p = new Point() { X = 42, Y = 13 };
```

Detailed Design

init accessors

An init only property (or indexer) is declared by using the `init` accessor in place of the `set` accessor:

```
class Student
{
    public string FirstName { get; init; }
    public string LastName { get; init; }
}
```

An instance property containing an `init` accessor is considered settable in the following circumstances, except when in a local function or lambda:

- During an object initializer
- During a `with` expression initializer
- Inside an instance constructor of the containing or derived type, on `this` or `base`
- Inside the `init` accessor of any property, on `this` or `base`
- Inside attribute usages with named parameters

The times above in which the `init` accessors are settable are collectively referred to in this document as the construction phase of the object.

This means the `Student` class can be used in the following ways:

```
var s = new Student()
{
    FirstName = "Jared",
    LastName = "Parosns",
};
s.LastName = "Parsons"; // Error: LastName is not settable
```

The rules around when `init` accessors are settable extend across type hierarchies. If the member is accessible and the object is known to be in the construction phase then the member is settable. That specifically allows for the following:

```
class Base
{
    public bool Value { get; init; }
}

class Derived : Base
{
    Derived()
    {
        // Not allowed with get only properties but allowed with init
        Value = true;
    }
}

class Consumption
{
    void Example()
    {
        var d = new Derived() { Value = true; };
    }
}
```

At the point an `init` accessor is invoked, the instance is known to be in the open construction phase. Hence an

`init` accessor is allowed to take the following actions in addition to what a normal `set` accessor can do:

1. Call other `init` accessors available through `this` or `base`
2. Assign `readonly` fields declared on the same type through `this`

```
class Complex
{
    readonly int Field1;
    int Field2;
    int Prop1 { get; init ; }
    int Prop2
    {
        get => 42;
        init
        {
            Field1 = 13; // okay
            Field2 = 13; // okay
            Prop1 = 13; // okay
        }
    }
}
```

The ability to assign `readonly` fields from an `init` accessor is limited to those fields declared on the same type as the accessor. It cannot be used to assign `readonly` fields in a base type. This rule ensures that type authors remain in control over the mutability behavior of their type. Developers who do not wish to utilize `init` cannot be impacted from other types choosing to do so:

```
class Base
{
    internal readonly int Field;
    internal int Property
    {
        get => Field;
        init => Field = value; // Okay
    }

    internal int OtherProperty { get; init; }
}

class Derived : Base
{
    internal readonly int DerivedField;
    internal int DerivedProperty
    {
        get => DerivedField;
        init
        {
            DerivedField = 42; // Okay
            Property = 0;      // Okay
            Field = 13;        // Error Field is readonly
        }
    }

    public Derived()
    {
        Property = 42; // Okay
        Field = 13;    // Error Field is readonly
    }
}
```

When `init` is used in a virtual property then all the overrides must also be marked as `init`. Likewise it is not possible to override a simple `set` with `init`.

```

class Base
{
    public virtual int Property { get; init; }
}

class C1 : Base
{
    public override int Property { get; init; }
}

class C2 : Base
{
    // Error: Property must have init to override Base.Property
    public override int Property { get; set; }
}

```

An `interface` declaration can also participate in `init` style initialization via the following pattern:

```

interface IPerson
{
    string Name { get; init; }
}

class Init
{
    void M<T>() where T : IPerson, new()
    {
        var local = new T()
        {
            Name = "Jared"
        };
        local.Name = "Jraed"; // Error
    }
}

```

Restrictions of this feature:

- The `init` accessor can only be used on instance properties
- A property cannot contain both an `init` and `set` accessor
- All overrides of a property must have `init` if the base had `init`. This rule also applies to interface implementation.

Readonly structs

`init` accessors (both auto-implemented accessors and manually-implemented accessors) are permitted on properties of `readonly struct`s, as well as `readonly` properties. `init` accessors are not permitted to be marked `readonly` themselves, in both `readonly` and non-`readonly` `struct` types.

```

readonly struct ReadonlyStruct1
{
    public int Prop1 { get; init; } // Allowed
}

struct ReadonlyStruct2
{
    public readonly int Prop2 { get; init; } // Allowed

    public int Prop3 { get; readonly init; } // Error
}

```

Metadata encoding

Property `init` accessors will be emitted as a standard `set` accessor with the return type marked with a modreq of `IsExternalInit`. This is a new type which will have the following definition:

```
namespace System.Runtime.CompilerServices
{
    public sealed class IsExternalInit
    {
    }
}
```

The compiler will match the type by full name. There is no requirement that it appear in the core library. If there are multiple types by this name then the compiler will tie break in the following order:

1. The one defined in the project being compiled
2. The one defined in corelib

If neither of these exist then a type ambiguity error will be issued.

The design for `IsExternalInit` is further covered in [this issue](#)

Questions

Breaking changes

One of the main pivot points in how this feature is encoded will come down to the following question:

Is it a binary breaking change to replace `init` with `set`?

Replacing `init` with `set` and thus making a property fully writable is never a source breaking change on a non-virtual property. It simply expands the set of scenarios where the property can be written. The only behavior in question is whether or not this remains a binary breaking change.

If we want to make the change of `init` to `set` a source and binary compatible change then it will force our hand on the modreq vs. attributes decision below because it will rule out modreqs as a solution. If on the other hand this is seen as a non-interesting then this will make the modreq vs. attribute decision less impactful.

Resolution This scenario is not seen as compelling by LDM.

Modreqs vs. attributes

The emit strategy for `init` property accessors must choose between using attributes or modreqs when emitting during metadata. These have different trade offs that need to be considered.

Annotating a property set accessor with a modreq declaration means CLI compliant compilers will ignore the accessor unless it understands the modreq. That means only compilers aware of `init` will read the member. Compilers unaware of `init` will ignore the `set` accessor and hence will not accidentally treat the property as read / write.

The downside of modreq is `init` becomes a part of the binary signature of the `set` accessor. Adding or removing `init` will break binary compatibility of the application.

Using attributes to annotate the `set` accessor means that only compilers which understand the attribute will know to limit access to it. A compiler unaware of `init` will see it as a simple read / write property and allow access.

This would seemingly mean this decision is a choice between extra safety at the expense of binary compatibility. Digging in a bit the extra safety is not exactly what it seems. It will not protect against the following circumstances:

1. Reflection over `public` members
2. The use of `dynamic`
3. Compilers that don't recognize modreqs

It should also be considered that, when we complete the IL verification rules for .NET 5, `init` will be one of those rules. That means extra enforcement will be gained from simply verifying compilers emitting verifiable IL.

The primary languages for .NET (C#, F# and VB) will all be updated to recognize these `init` accessors. Hence the only realistic scenario here is when a C# 9 compiler emits `init` properties and they are seen by an older toolset such as C# 8, VB 15, etc ... C# 8. That is the trade off to consider and weigh against binary compatibility.

Note This discussion primarily applies to members only, not to fields. While `init` fields were rejected by LDM they are still interesting to consider for the modreq vs. attribute discussion. The `init` feature for fields is a relaxation of the existing restriction of `readonly`. That means if we emit the fields as `readonly` + an attribute there is no risk of older compilers mis-using the field because they would already recognize `readonly`. Hence using a modreq here doesn't add any extra protection.

Resolution The feature will use a modreq to encode the property `init` setter. The compelling factors were (in no particular order):

- Desire to discourage older compilers from violating `init` semantics
- Desire to make adding or removing `init` in a `virtual` declaration or `interface` both a source and binary breaking change.

Given there was also no significant support for removing `init` to be a binary compatible change it made the choice of using modreq straight forward.

init vs. initonly

There were three syntax forms which got significant consideration during our LDM meeting:

```
// 1. Use init
int Option1 { get; init; }
// 2. Use init set
int Option2 { get; init set; }
// 3. Use initonly
int Option3 { get; initonly; }
```

Resolution There was no syntax which was overwhelmingly favored in LDM.

One point which got significant attention was how the choice of syntax would impact our ability to do `init` members as a general feature in the future. Choosing option 1 would mean that it would be difficult to define a property which had an `init` style `get` method in the future. Eventually it was decided that if we decided to go forward with general `init` members in future, we could allow `init` to be a modifier in the property accessor list as well as a short hand for `init set`. Essentially the following two declarations would be identical.

```
int Property1 { get; init; }
int Property1 { get; init set; }
```

The decision was made to move forward with `init` as a standalone accessor in the property accessor list.

Warn on failed init

Consider the following scenario. A type declares an `init` only member which is not set in the constructor. Should the code which constructs the object get a warning if they failed to initialize the value?

At that point it is clear the field will never be set and hence has a lot of similarities with the warning around

failing to initialize `private` data. Hence a warning would seemingly have some value here?

There are significant downsides to this warning though:

1. It complicates the compatibility story of changing `readonly` to `init`.
2. It requires carrying additional metadata around to denote the members which are required to be initialized by the caller.

Further if we believe there is value here in the overall scenario of forcing object creators to be warned / error'd about specific fields then this likely makes sense as a general feature. There is no reason it should be limited to just `init` members.

Resolution There will be no warning on consumption of `init` fields and properties.

LDM wants to have a broader discussion on the idea of required fields and properties. That may cause us to come back and reconsider our position on `init` members and validation.

Allow init as a field modifier

In the same way `init` can serve as a property accessor it could also serve as a designation on fields to give them similar behaviors as `init` properties. That would allow for the field to be assigned before construction was complete by the type, derived types, or object initializers.

```
class Student
{
    public init string FirstName;
    public init string LastName;
}

var s = new Student()
{
    FirstName = "Jarde",
    LastName = "Parsons",
}

s.FirstName = "Jared"; // Error FirstName is readonly
```

In metadata these fields would be marked in the same way as `readonly` fields but with an additional attribute or modreq to indicate they are `init` style fields.

Resolution LDM agrees this proposal is sound but overall the scenario felt disjoint from properties. The decision was to proceed only with `init` properties for now. This has a suitable level of flexibility as an `init` property can mutate a `readonly` field on the declaring type of the property. This will be reconsidered if there is significant customer feedback that justifies the scenario.

Allow init as a type modifier

In the same way the `readonly` modifier can be applied to a `struct` to automatically declare all fields as `readonly`, the `init` only modifier can be declared on a `struct` or `class` to automatically mark all fields as `init`. This means the following two type declarations are equivalent:

```

struct Point
{
    public init int X;
    public init int Y;
}

// vs.

init struct Point
{
    public int X;
    public int Y;
}

```

Resolution This feature is too *cute* here and conflicts with the `readonly struct` feature on which it is based. The `readonly struct` feature is simple in that it applies `readonly` to all members: fields, methods, etc ... The `init struct` feature would only apply to properties. This actually ends up making it confusing for users.

Given that `init` is only valid on certain aspects of a type, we rejected the idea of having it as a type modifier.

Considerations

Compatibility

The `init` feature is designed to be compatible with existing `get` only properties. Specifically it is meant to be a completely additive change for a property which is `get` only today but desires more flexible object creation semantics.

For example consider the following type:

```

class Name
{
    public string First { get; }
    public string Last { get; }

    public Name(string first, string last)
    {
        First = first;
        Last = last;
    }
}

```

Adding `init` to these properties is a non-breaking change:

```

class Name
{
    public string First { get; init; }
    public string Last { get; init; }

    public Name(string first, string last)
    {
        First = first;
        Last = last;
    }
}

```

IL verification

When .NET Core decides to re-implement IL verification, the rules will need to be adjusted to account for `init` members. This will need to be included in the rule changes for non-mutating access to `readonly` data.

The IL verification rules will need to be broken into two parts:

1. Allowing `init` members to set a `readonly` field.
2. Determining when an `init` member can be legally called.

The first is a simple adjustment to the existing rules. The IL verifier can be taught to recognize `init` members and from there it just needs to consider a `readonly` field to be settable on `this` in such a member.

The second rule is more complicated. In the simple case of object initializers the rule is straight forward. It should be legal to call `init` members when the result of a `new` expression is still on the stack. That is until the value has been stored in a local, array element or field or passed as an argument to another method it will still be legal to call `init` members. This ensures that once the result of the `new` expression is published to a named identifier (other than `this`) then it will no longer be legal to call `init` members.

The more complicated case though is when we mix `init` members, object initializers and `await`. That can cause the newly created object to be temporarily hoisted into a state machine and hence put into a field.

```
var student = new Student()
{
    Name = await SomeMethod()
};
```

Here the result of `new Student()` will be hoisted into a state machine as a field before the set of `Name` occurs. The compiler will need to mark such hoisted fields in a way that the IL verifier understands they're not user accessible and hence doesn't violate the intended semantics of `init`.

init members

The `init` modifier could be extended to apply to all instance members. This would generalize the concept of `init` during object construction and allow types to declare helper methods that could participate in the construction process to initialize `init` fields and properties.

Such members would have all the restrictions that an `init` accessor does in this design. The need is questionable though and this can be safely added in a future version of the language in a compatible manner.

Generate three accessors

One potential implementation of `init` properties is to make `init` completely separate from `set`. That means that a property can potentially have three different accessors: `get`, `set`, and `init`.

This has the potential advantage of allowing the use of `modreq` to enforce correctness while maintaining binary compatibility. The implementation would roughly be the following:

1. An `init` accessor is always emitted if there is a `set`. When not defined by the developer it is simply a reference to `set`.
2. The set of a property in an object initializer will always use `init` if present but fall back to `set` if it's missing.

This means that a developer can always safely delete `init` from a property.

The downside of this design is that is only useful if `init` is **always** emitted when there is a `set`. The language can't know if `init` was deleted in the past, it has to assume it was and hence the `init` must always be emitted. That would cause a significant metadata expansion and is simply not worth the cost of the compatibility here.

Target-typed new expressions

12/28/2021 • 3 minutes to read • [Edit Online](#)

Summary

Do not require type specification for constructors when the type is known.

Motivation

Allow field initialization without duplicating the type.

```
Dictionary<string, List<int>> field = new() {  
    { "item1", new() { 1, 2, 3 } }  
};
```

Allow omitting the type when it can be inferred from usage.

```
XmlReader.Create(reader, new() { IgnoreWhitespace = true });
```

Instantiate an object without spelling out the type.

```
private readonly static object s_syncObj = new();
```

Specification

A new syntactic form, *target_typed_new* of the *object_creation_expression* is accepted in which the *type* is optional.

```
object_creation_expression  
    : 'new' type '(' argument_list? ')' object_or_collection_initializer?  
    | 'new' type object_or_collection_initializer  
    | target_typed_new  
    ;  
target_typed_new  
    : 'new' '(' argument_list? ')' object_or_collection_initializer?  
    ;
```

A *target_typed_new* expression does not have a type. However, there is a new *object creation conversion* that is an implicit conversion from expression, that exists from a *target_typed_new* to every type.

Given a target type T , the type T_0 is T 's underlying type if T is an instance of `System.Nullable`. Otherwise T_0 is T . The meaning of a *target_typed_new* expression that is converted to the type T is the same as the meaning of a corresponding *object_creation_expression* that specifies T_0 as the type.

It is a compile-time error if a *target_typed_new* is used as an operand of a unary or binary operator, or if it is used where it is not subject to an *object creation conversion*.

Open Issue: should we allow delegates and tuples as the target-type?

The above rules include delegates (a reference type) and tuples (a struct type). Although both types are

constructible, if the type is inferable, an anonymous function or a tuple literal can already be used.

```
(int a, int b) t = new(1, 2); // "new" is redundant
Action a = new(() => {}); // "new" is redundant

(int a, int b) t = new(); // OK; same as (0, 0)
Action a = new(); // no constructor found
```

Miscellaneous

The following are consequences of the specification:

- `throw new()` is allowed (the target type is `System.Exception`)
- Target-typed `new` is not allowed with binary operators.
- It is disallowed when there is no type to target: unary operators, collection of a `foreach`, in a `using`, in a deconstruction, in an `await` expression, as an anonymous type property (`new { Prop = new() }`), in a `lock` statement, in a `sizeof`, in a `fixed` statement, in a member access (`new().field`), in a dynamically dispatched operation (`someDynamic.Method(new())`), in a LINQ query, as the operand of the `is` operator, as the left operand of the `??` operator, ...
- It is also disallowed as a `ref`.
- The following kinds of types are not permitted as targets of the conversion
 - **Enum types:** `new()` will work (as `new Enum()` works to give the default value), but `new(1)` will not work as enum types do not have a constructor.
 - **Interface types:** This would work the same as the corresponding creation expression for COM types.
 - **Array types:** arrays need a special syntax to provide the length.
 - **dynamic:** we don't allow `new dynamic()`, so we don't allow `new()` with `dynamic` as a target type.
 - **tuples:** These have the same meaning as an object creation using the underlying type.
 - All the other types that are not permitted in the *object_creation_expression* are excluded as well, for instance, pointer types.

Drawbacks

There were some concerns with target-typed `new` creating new categories of breaking changes, but we already have that with `null` and `default`, and that has not been a significant problem.

Alternatives

Most of complaints about types being too long to duplicate in field initialization is about *type arguments* not the type itself, we could infer only type arguments like `new Dictionary(...)` (or similar) and infer type arguments locally from arguments or the collection initializer.

Questions

- Should we forbid usages in expression trees? (no)
- How the feature interacts with `dynamic` arguments? (no special treatment)
- How IntelliSense should work with `new()`? (only when there is a single target-type)

Module Initializers

12/28/2021 • 2 minutes to read • [Edit Online](#)

Summary

Although the .NET platform has a [feature](#) that directly supports writing initialization code for the assembly (technically, the module), it is not exposed in C#. This is a rather niche scenario, but once you run into it the solutions appear to be pretty painful. There are reports of [a number of customers](#) (inside and outside Microsoft) struggling with the problem, and there are no doubt more undocumented cases.

Motivation

- Enable libraries to do eager, one-time initialization when loaded, with minimal overhead and without the user needing to explicitly call anything
- One particular pain point of current `static` constructor approaches is that the runtime must do additional checks on usage of a type with a static constructor, in order to decide whether the static constructor needs to be run or not. This adds measurable overhead.
- Enable source generators to run some global initialization logic without the user needing to explicitly call anything

Detailed design

A method can be designated as a module initializer by decorating it with a `[ModuleInitializer]` attribute.

```
using System;
namespace System.Runtime.CompilerServices
{
    [AttributeUsage(AttributeTargets.Method, AllowMultiple = false)]
    public sealed class ModuleInitializerAttribute : Attribute { }
}
```

The attribute can be used like this:

```
using System.Runtime.CompilerServices;
class C
{
    [ModuleInitializer]
    internal static void M1()
    {
        // ...
    }
}
```

Some requirements are imposed on the method targeted with this attribute:

1. The method must be `static`.
2. The method must be parameterless.
3. The method must return `void`.
4. The method must not be generic or be contained in a generic type.
5. The method must be accessible from the containing module.
 - This means the method's effective accessibility must be `internal` or `public`.

- This also means the method cannot be a local function.

When one or more valid methods with this attribute are found in a compilation, the compiler will emit a module initializer which calls each of the attributed methods. The calls will be emitted in a reserved, but deterministic order.

Drawbacks

Why should we *not* do this?

- Perhaps the existing third-party tooling for "injecting" module initializers is sufficient for users who have been asking for this feature.

Extending Partial Methods

12/28/2021 • 5 minutes to read • [Edit Online](#)

Summary

This proposal aims to remove all restrictions around the signatures of `partial` methods in C#. The goal being to expand the set of scenarios in which these methods can work with source generators as well as being a more general declaration form for C# methods.

See also the [original partial methods specification](#).

Motivation

C# has limited support for developers splitting methods into declarations and definitions / implementations.

```
partial class C
{
    // The declaration of C.M
    partial void M(string message);
}

partial class C
{
    // The definition of C.M
    partial void M(string message) => Console.WriteLine(message);
}
```

One behavior of `partial` methods is that when the definition is absent then the language will simply erase any calls to the `partial` method. Essentially it behaves like a call to a `[Conditional]` method where the condition was evaluated to false.

```
partial class D
{
    partial void M(string message);

    void Example()
    {
        M(GetIt()); // Call to M and GetIt erased at compile time
    }

    string GetIt() => "Hello World";
}
```

The original motivation for this feature was source generation in the form of designer generated code. Users were constantly editing the generated code because they wanted to hook some aspect of the generated code. Most notably parts of the Windows Forms startup process, after components were initialized.

Editing the generated code was error prone because any action which caused the designer to regenerate the code would cause the user edit to be erased. The `partial` method feature eased this tension because it allowed designers to emit hooks in the form of `partial` methods.

Designers could emit hooks like `partial void OnComponentInit()` and developers could define declarations for them or not define them. In either case though the generated code would compile and developers who were interested in the process could hook in as needed.

This does mean that partial methods have several restrictions:

1. Must have a `void` return type.
2. Cannot have `out` parameters.
3. Cannot have any accessibility (implicitly `private`).

These restrictions exist because the language must be able to emit code when the call site is erased. Given they can be erased `private` is the only possible accessibility because the member can't be exposed in assembly metadata. These restrictions also serve to limit the set of scenarios in which `partial` methods can be applied.

The proposal here is to remove all of the existing restrictions around `partial` methods. Essentially let them have `out`, non-void return types or any type of accessibility. Such `partial` declarations would then have the added requirement that a definition must exist. That means the language does not have to consider the impact of erasing the call sites.

This would expand the set of generator scenarios that `partial` methods could participate in and hence link in nicely with our source generators feature. For example a regex could be defined using the following pattern:

```
[RegexGenerated("(dog|cat|fish)")]  
partial bool IsPetMatch(string input);
```

This gives both the developer a simple declarative way of opting into generators as well as giving generators a very easy set of declarations to look through in the source code to drive their generated output.

Compare that with the difficulty that a generator would have hooking up the following snippet of code.

```
var regex = new RegularExpression("(dog|cat|fish)");  
if (regex.IsMatch(someInput))  
{  
  
}
```

Given that the compiler doesn't allow generators to modify code hooking up this pattern would be pretty much impossible for generators. They would need to resort to reflection in the `IsMatch` implementation, or asking users to change their call sites to a new method + refactor the regex to pass the string literal as an argument. It's pretty messy.

Detailed Design

The language will change to allow `partial` methods to be annotated with an explicit accessibility modifier. This means they can be labeled as `private`, `public`, etc ...

When a `partial` method has an explicit accessibility modifier though the language will require that the declaration has a matching definition even when the accessibility is `private`:

```

partial class C
{
    // Okay because no definition is required here
    partial void M1();

    // Okay because M2 has a definition
    private partial void M2();

    // Error: partial method M3 must have a definition
    private partial void M3();
}

partial class C
{
    private partial void M2() { }
}

```

Further the language will remove all restrictions on what can appear on a `partial` method which has an explicit accessibility. Such declarations can contain non-void return types, `out` parameters, `extern` modifier, etc ... These signatures will have the full expressivity of the C# language.

```

partial class D
{
    // Okay
    internal partial bool TryParse(string s, out int i);
}

partial class D
{
    internal partial bool TryParse(string s, out int i) { }
}

```

This explicitly allows for `partial` methods to participate in `overrides` and `interface` implementations:

```

interface IStudent
{
    string GetName();
}

partial class C : IStudent
{
    public virtual partial string GetName();
}

partial class C
{
    public virtual partial string GetName() => "Jarde";
}

```

The compiler will change the error it emits when a `partial` method contains an illegal element to essentially say:

Cannot use `ref` on a `partial` method that lacks explicit accessibility

This will help point developers in the right direction when using this feature.

Restrictions:

- `partial` declarations with explicit accessibility must have a definition
- `partial` declarations and definition signatures must match on all method and parameter modifiers. The only

aspects which can differ are parameter names and attribute lists (this is not new but rather an existing requirement of `partial` methods).

Questions

partial on all members

Given that we're expanding `partial` to be more friendly to source generators should we also expand it to work on all class members? For example should we be able to declare `partial` constructors, operators, etc ...

Resolution The idea is sound but at this point in the C# 9 schedule we're trying to avoid unnecessary feature creep. Want to solve the immediate problem of expanding the feature to work with modern source generators.

Extending `partial` to support other members will be considered for the C# 10 release. Seems likely that we will consider this extension.

Use abstract instead of partial

The crux of this proposal is essentially ensuring that a declaration has a corresponding definition / implementation. Given that should we use `abstract` since it's already a language keyword that forces the developer to think about having an implementation?

Resolution There was a healthy discussion about this but eventually it was decided against. Yes the requirements are familiar but the concepts are significantly different. Could easily lead the developer to believe they were creating virtual slots when they were not doing so.

Static anonymous functions

12/28/2021 • 2 minutes to read • [Edit Online](#)

Summary

Allow a 'static' modifier on lambdas and anonymous methods, which disallows capture of locals or instance state from containing scopes.

Motivation

Avoid unintentionally capturing state from the enclosing context, which can result in unexpected retention of captured objects or unexpected additional allocations.

Detailed design

A lambda or anonymous method may have a `static` modifier. The `static` modifier indicates that the lambda or anonymous method is a *static anonymous function*.

A *static anonymous function* cannot capture state from the enclosing scope. As a result, locals, parameters, and `this` from the enclosing scope are not available within a *static anonymous function*.

A *static anonymous function* cannot reference instance members from an implicit or explicit `this` or `base` reference.

A *static anonymous function* may reference `static` members from the enclosing scope.

A *static anonymous function* may reference `constant` definitions from the enclosing scope.

`nameof()` in a *static anonymous function* may reference locals, parameters, or `this` or `base` from the enclosing scope.

Accessibility rules for `private` members in the enclosing scope are the same for `static` and non-`static` anonymous functions.

No guarantee is made as to whether a *static anonymous function* definition is emitted as a `static` method in metadata. This is left up to the compiler implementation to optimize.

A non-`static` local function or anonymous function can capture state from an enclosing *static anonymous function* but cannot capture state outside the enclosing *static anonymous function*.

Removing the `static` modifier from an anonymous function in a valid program does not change the meaning of the program.

Target-Typed Conditional Expression

12/28/2021 • 3 minutes to read • [Edit Online](#)

Conditional Expression Conversion

For a conditional expression `c ? e1 : e2`, when

1. there is no common type for `e1` and `e2`, or
2. for which a common type exists but one of the expressions `e1` or `e2` has no implicit conversion to that type

we define a new implicit *conditional expression conversion* that permits an implicit conversion from the conditional expression to any type `T` for which there is a conversion-from-expression from `e1` to `T` and also from `e2` to `T`. It is an error if a conditional expression neither has a common type between `e1` and `e2` nor is subject to a *conditional expression conversion*.

Better Conversion from Expression

We change

Better conversion from expression

Given an implicit conversion `c1` that converts from an expression `E` to a type `T1`, and an implicit conversion `c2` that converts from an expression `E` to a type `T2`, `c1` is a **better conversion** than `c2` if `E` does not exactly match `T2` and at least one of the following holds:

- `E` exactly matches `T1` ([Exactly matching Expression](#))
- `T1` is a better conversion target than `T2` ([Better conversion target](#))

to

Better conversion from expression

Given an implicit conversion `c1` that converts from an expression `E` to a type `T1`, and an implicit conversion `c2` that converts from an expression `E` to a type `T2`, `c1` is a **better conversion** than `c2` if `E` does not exactly match `T2` and at least one of the following holds:

- `E` exactly matches `T1` ([Exactly matching Expression](#))
- `c1` is not a *conditional expression conversion* and `c2` is a *conditional expression conversion*.
- `T1` is a better conversion target than `T2` ([Better conversion target](#)) and either `c1` and `c2` are both *conditional expression conversions* or neither is a *conditional expression conversion*.

Cast Expression

The current C# language specification says

A *cast_expression* of the form `(T)E`, where `T` is a *type* and `E` is a *unary_expression*, performs an explicit conversion ([Explicit conversions](#)) of the value of `E` to type `T`.

In the presence of the *conditional expression conversion* there may be more than one possible conversion from `E` to `T`. With the addition of *conditional expression conversion*, we prefer any other conversion to a *conditional expression conversion*, and use the *conditional expression conversion* only as a last resort.

Design Notes

The reason for the change to *Better conversion from expression* is to handle a case such as this:

```
M(b ? 1 : 2);

void M(short);
void M(long);
```

This approach does have two small downsides. First, it is not quite the same as the switch expression:

```
M(b ? 1 : 2); // calls M(long)
M(b switch { true => 1, false => 2 }); // calls M(short)
```

This is still a breaking change, but its scope is less likely to affect real programs:

```
M(b ? 1 : 2, 1); // calls M(long, long) without this feature; ambiguous with this feature.

M(short, short);
M(long, long);
```

This becomes ambiguous because the conversion to `long` is better for the first argument (because it does not use the *conditional expression conversion*), but the conversion to `short` is better for the second argument (because `short` is a *better conversion target* than `long`). This breaking change seems less serious because it does not silently change the behavior of an existing program.

The reason for the notes on the cast expression is to handle a case such as this:

```
_ = (short)(b ? 1 : 2);
```

This program currently uses the explicit conversion from `int` to `short`, and we want to preserve the current language meaning of this program. The change would be unobservable at runtime, but with the following program the change would be observable:

```
_ = (A)(b ? c : d);
```

where `c` is of type `C`, `d` is of type `D`, and there is an implicit user-defined conversion from `C` to `D`, and an implicit user-defined conversion from `D` to `A`, and an implicit user-defined conversion from `C` to `A`. If this code is compiled before C# 9.0, when `b` is true we convert from `C` to `D` then to `A`. If we use the *conditional expression conversion*, then when `b` is true we convert from `C` to `A` directly, which executes a different sequence of user code. Therefore we treat the *conditional expression conversion* as a last resort in a cast, to preserve existing behavior.

Covariant returns

12/28/2021 • 10 minutes to read • [Edit Online](#)

Summary

Support *covariant return types*. Specifically, permit the override of a method to declare a more derived return type than the method it overrides, and similarly to permit the override of a read-only property to declare a more derived type. Override declarations appearing in more derived types would be required to provide a return type at least as specific as that appearing in overrides in its base types. Callers of the method or property would statically receive the more refined return type from an invocation.

Motivation

It is a common pattern in code that different method names have to be invented to work around the language constraint that overrides must return the same type as the overridden method.

This would be useful in the factory pattern. For example, in the Roslyn code base we would have

```
class Compilation ...
{
    public virtual Compilation WithOptions(Options options)...
}
```

```
class CSharpCompilation : Compilation
{
    public override CSharpCompilation WithOptions(Options options)...
}
```

Detailed design

This is a specification for [covariant return types](#) in C#. Our intent is to permit the override of a method to return a more derived return type than the method it overrides, and similarly to permit the override of a read-only property to return a more derived return type. Callers of the method or property would statically receive the more refined return type from an invocation, and overrides appearing in more derived types would be required to provide a return type at least as specific as that appearing in overrides in its base types.

Class Method Override

The [existing constraint on class override](#) methods

- The override method and the overridden base method have the same return type.

is modified to

- The override method must have a return type that is convertible by an identity conversion or (if the method has a value return - not a [ref return](#)) implicit reference conversion to the return type of the overridden base method.

And the following additional requirements are appended to that list:

- The override method must have a return type that is convertible by an identity conversion or (if the method has a value return - not a [ref return](#)) implicit reference conversion to the return type of every override of the overridden base method that is declared in a (direct or indirect) base type of the override method.
- The override method's return type must be at least as accessible as the override method ([Accessibility domains](#)).

This constraint permits an override method in a `private` class to have a `private` return type. However it requires a `public` override method in a `public` type to have a `public` return type.

Class Property and Indexer Override

The [existing constraint on class override](#) properties

An overriding property declaration shall specify the exact same accessibility modifiers and name as the inherited property, and there shall be an identity conversion ~~between the type of the overriding and the inherited property~~. If the inherited property has only a single accessor (i.e., if the inherited property is read-only or write-only), the overriding property shall include only that accessor. If the inherited property includes both accessors (i.e., if the inherited property is read-write), the overriding property can include either a single accessor or both accessors.

is modified to

An overriding property declaration shall specify the exact same accessibility modifiers and name as the inherited property, and there shall be an identity conversion **or (if the inherited property is read-only and has a value return - not a [ref return](#)) implicit reference conversion from the type of the overriding property to the type of the inherited property**. If the inherited property has only a single accessor (i.e., if the inherited property is read-only or write-only), the overriding property shall include only that accessor. If the inherited property includes both accessors (i.e., if the inherited property is read-write), the overriding property can include either a single accessor or both accessors. **The overriding property's type must be at least as accessible as the overriding property ([Accessibility domains](#)).**

The remainder of the draft specification below proposes a further extension to covariant returns of interface methods to be considered later.

Interface Method, Property, and Indexer Override

Adding to the kinds of members that are permitted in an interface with the addition of the DIM feature in C# 8.0, we further add support for `override` members along with covariant returns. These follow the rules of `override` members as specified for classes, with the following differences:

The following text in classes:

The method overridden by an override declaration is known as the ***overridden base method***. For an override method `M` declared in a class `C`, the overridden base method is determined by examining each base class of `C`, starting with the direct base class of `C` and continuing with each successive direct base class, until in a given base class type at least one accessible method is located which has the same signature as `M` after substitution of type arguments.

is given the corresponding specification for interfaces:

The method overridden by an override declaration is known as the ***overridden base method***. For an override method `M` declared in an interface `I`, the overridden base method is determined by examining each direct or indirect base interface of `I`, collecting the set of interfaces declaring an accessible method

which has the same signature as `M` after substitution of type arguments. If this set of interfaces has a *most derived type*, to which there is an identity or implicit reference conversion from every type in this set, and that type contains a unique such method declaration, then that is the *overridden base method*.

We similarly permit `override` properties and indexers in interfaces as specified for classes in *15.7.6 Virtual, sealed, override, and abstract accessors*.

Name Lookup

Name lookup in the presence of class `override` declarations currently modify the result of name lookup by imposing on the found member details from the most derived `override` declaration in the class hierarchy starting from the type of the identifier's qualifier (or `this` when there is no qualifier). For example, in *12.6.2.2 Corresponding parameters* we have

For virtual methods and indexers defined in classes, the parameter list is picked from the first declaration or override of the function member found when starting with the static type of the receiver, and searching through its base classes.

to this we add

For virtual methods and indexers defined in interfaces, the parameter list is picked from the declaration or override of the function member found in the most derived type among those types containing the declaration of override of the function member. It is a compile-time error if no unique such type exists.

For the result type of a property or indexer access, the existing text

- If `I` identifies an instance property, then the result is a property access with an associated instance expression of `E` and an associated type that is the type of the property. If `T` is a class type, the associated type is picked from the first declaration or override of the property found when starting with `T`, and searching through its base classes.

is augmented with

If `T` is an interface type, the associated type is picked from the declaration or override of the property found in the most derived of `T` or its direct or indirect base interfaces. It is a compile-time error if no unique such type exists.

A similar change should be made in *12.7.7.3 Indexer access*

In *12.7.6 Invocation expressions* we augment the existing text

- Otherwise, the result is a value, with an associated type of the return type of the method or delegate. If the invocation is of an instance method, and the receiver is of a class type `T`, the associated type is picked from the first declaration or override of the method found when starting with `T` and searching through its base classes.

with

If the invocation is of an instance method, and the receiver is of an interface type `T`, the associated type is picked from the declaration or override of the method found in the most derived interface from among `T` and its direct and indirect base interfaces. It is a compile-time error if no unique such type exists.

Implicit Interface Implementations

This section of the specification

For purposes of interface mapping, a class member `A` matches an interface member `B` when:

- `A` and `B` are methods, and the name, type, and formal parameter lists of `A` and `B` are identical.
- `A` and `B` are properties, the name and type of `A` and `B` are identical, and `A` has the same accessors as `B` (`A` is permitted to have additional accessors if it is not an explicit interface member implementation).
- `A` and `B` are events, and the name and type of `A` and `B` are identical.
- `A` and `B` are indexers, the type and formal parameter lists of `A` and `B` are identical, and `A` has the same accessors as `B` (`A` is permitted to have additional accessors if it is not an explicit interface member implementation).

is modified as follows:

For purposes of interface mapping, a class member `A` matches an interface member `B` when:

- `A` and `B` are methods, and the name and formal parameter lists of `A` and `B` are identical, and the return type of `A` is convertible to the return type of `B` via an identity of implicit reference conversion to the return type of `B`.
- `A` and `B` are properties, the name of `A` and `B` are identical, `A` has the same accessors as `B` (`A` is permitted to have additional accessors if it is not an explicit interface member implementation), and the type of `A` is convertible to the return type of `B` via an identity conversion or, if `A` is a readonly property, an implicit reference conversion.
- `A` and `B` are events, and the name and type of `A` and `B` are identical.
- `A` and `B` are indexers, the formal parameter lists of `A` and `B` are identical, `A` has the same accessors as `B` (`A` is permitted to have additional accessors if it is not an explicit interface member implementation), and the type of `A` is convertible to the return type of `B` via an identity conversion or, if `A` is a readonly indexer, an implicit reference conversion.

This is technically a breaking change, as the program below prints "C1.M" today, but would print "C2.M" under the proposed revision.

```
using System;

interface I1 { object M(); }
class C1 : I1 { public object M() { return "C1.M"; } }
class C2 : C1, I1 { public new string M() { return "C2.M"; } }
class Program
{
    static void Main()
    {
        I1 i = new C2();
        Console.WriteLine(i.M());
    }
}
```

Due to this breaking change, we might consider not supporting covariant return types on implicit implementations.

Constraints on Interface Implementation

We will need a rule that an explicit interface implementation must declare a return type no less derived than the return type declared in any override in its base interfaces.

API Compatibility Implications

TBD

Open Issues

The specification does not say how the caller gets the more refined return type. Presumably that would be done in a way similar to the way that callers get the most derived override's parameter specifications.

If we have the following interfaces:

```
interface I1 { I1 M(); }
interface I2 { I2 M(); }
interface I3: I1, I2 { override I3 M(); }
```

Note that in `I3`, the methods `I1.M()` and `I2.M()` have been "merged". When implementing `I3`, it is necessary to implement them both together.

Generally, we require an explicit implementation to refer to the original method. The question is, in a class

```
class C : I1, I2, I3
{
    C IN.M();
}
```

What does that mean here? What should *N* be?

I suggest that we permit implementing either `I1.M` or `I2.M` (but not both), and treat that as an implementation of both.

Drawbacks

- [] Every language change must pay for itself.
- [] We should ensure that the performance is reasonable, even in the case of deep inheritance hierarchies
- [] We should ensure that artifacts of the translation strategy do not affect language semantics, even when consuming new IL from old compilers.

Alternatives

We could relax the language rules slightly to allow, in source,

```
abstract class Cloneable
{
    public abstract Cloneable Clone();
}

class Digit : Cloneable
{
    public override Cloneable Clone()
    {
        return this.Clone();
    }

    public new Digit Clone() // Error: 'Digit' already defines a member called 'Clone' with the same
parameter types
    {
        return this;
    }
}
```

Unresolved questions

- [] How will APIs that have been compiled to use this feature work in older versions of the language?

Design meetings

- some discussion at <https://github.com/dotnet/roslyn/issues/357>.
- <https://github.com/dotnet/csharplang/blob/master/meetings/2020/LDM-2020-01-08.md>
- Offline discussion toward a decision to support overriding of class methods only in C# 9.0.

Extension `GetEnumerator` support for `foreach` loops.

12/28/2021 • 5 minutes to read • [Edit Online](#)

Summary

Allow `foreach` loops to recognize an extension method `GetEnumerator` method that otherwise satisfies the `foreach` pattern, and loop over the expression when it would otherwise be an error.

Motivation

This will bring `foreach` inline with how other features in C# are implemented, including `async` and pattern-based deconstruction.

Detailed design

The spec change is relatively straightforward. We modify `The foreach statement` section to this text:

The compile-time processing of a `foreach` statement first determines the *collection type*, *enumerator type* and *element type* of the expression. This determination proceeds as follows:

- If the type `x` of *expression* is an array type then there is an implicit reference conversion from `x` to the `IEnumerable` interface (since `System.Array` implements this interface). The *collection type* is the `IEnumerable` interface, the *enumerator type* is the `IEnumerator` interface and the *element type* is the element type of the array type `x`.
- If the type `x` of *expression* is `dynamic` then there is an implicit conversion from *expression* to the `IEnumerable` interface ([Implicit dynamic conversions](#)). The *collection type* is the `IEnumerable` interface and the *enumerator type* is the `IEnumerator` interface. If the `var` identifier is given as the *local_variable_type* then the *element type* is `dynamic`, otherwise it is `object`.
- Otherwise, determine whether the type `x` has an appropriate `GetEnumerator` method:
 - Perform member lookup on the type `x` with identifier `GetEnumerator` and no type arguments. If the member lookup does not produce a match, or it produces an ambiguity, or produces a match that is not a method group, check for an enumerable interface as described below. It is recommended that a warning be issued if member lookup produces anything except a method group or no match.
 - Perform overload resolution using the resulting method group and an empty argument list. If overload resolution results in no applicable methods, results in an ambiguity, or results in a single best method but that method is either static or not public, check for an enumerable interface as described below. It is recommended that a warning be issued if overload resolution produces anything except an unambiguous public instance method or no applicable methods.
 - If the return type `E` of the `GetEnumerator` method is not a class, struct or interface type, an error is produced and no further steps are taken.
 - Member lookup is performed on `E` with the identifier `Current` and no type arguments. If the member lookup produces no match, the result is an error, or the result is anything except a public instance property that permits reading, an error is produced and no further steps are taken.
 - Member lookup is performed on `E` with the identifier `MoveNext` and no type arguments. If the

member lookup produces no match, the result is an error, or the result is anything except a method group, an error is produced and no further steps are taken.

- Overload resolution is performed on the method group with an empty argument list. If overload resolution results in no applicable methods, results in an ambiguity, or results in a single best method but that method is either static or not public, or its return type is not `bool`, an error is produced and no further steps are taken.

- The **collection type** is `X`, the **enumerator type** is `E`, and the **element type** is the type of the `Current` property.

- Otherwise, check for an enumerable interface:

- If among all the types `Ti` for which there is an implicit conversion from `X` to `IEnumerable<Ti>`, there is a unique type `T` such that `T` is not `dynamic` and for all the other `Ti` there is an implicit conversion from `IEnumerable<T>` to `IEnumerable<Ti>`, then the **collection type** is the interface `IEnumerable<T>`, the **enumerator type** is the interface `IEnumerator<T>`, and the **element type** is `T`.

- Otherwise, if there is more than one such type `T`, then an error is produced and no further steps are taken.

- Otherwise, if there is an implicit conversion from `X` to the `System.Collections.IEnumerable` interface, then the **collection type** is this interface, the **enumerator type** is the interface `System.Collections.IEnumerator`, and the **element type** is `object`.

- Otherwise, determine whether the type 'X' has an appropriate `GetEnumerator` extension method:

- Perform extension method lookup on the type `X` with identifier `GetEnumerator`. If the member lookup does not produce a match, or it produces an ambiguity, or produces a match which is not a method group, an error is produced and no further steps are taken. It is recommended that a warning be issues if member lookup produces anything except a method group or no match.

- Perform overload resolution using the resulting method group and a single argument of type `X`. If overload resolution produces no applicable methods, results in an ambiguity, or results in a single best method but that method is not accessible, an error is produced and no further steps are taken.

- This resolution permits the first argument to be passed by ref if `X` is a struct type, and the ref kind is `in`.

- If the return type `E` of the `GetEnumerator` method is not a class, struct or interface type, an error is produced and no further steps are taken.

- Member lookup is performed on `E` with the identifier `Current` and no type arguments. If the member lookup produces no match, the result is an error, or the result is anything except a public instance property that permits reading, an error is produced and no further steps are taken.

- Member lookup is performed on `E` with the identifier `MoveNext` and no type arguments. If the member lookup produces no match, the result is an error, or the result is anything except a method group, an error is produced and no further steps are taken.

- Overload resolution is performed on the method group with an empty argument list. If overload resolution results in no applicable methods, results in an ambiguity, or results in a single best method but that method is either static or not public, or its return type is not `bool`, an error is produced and no further steps are taken.

- The **collection type** is `X`, the **enumerator type** is `E`, and the **element type** is the type of the `Current` property.

- Otherwise, an error is produced and no further steps are taken.

For `await foreach`, the rules are similarly modified. The only change that is required to that spec is removing the `Extension methods do not contribute.` line from the description, as the rest of that spec is based on the

above rules with different names substituted for the pattern methods.

Drawbacks

Every change adds additional complexity to the language, and this potentially allows things that weren't designed to be `foreach` ed to be `foreach` ed, like `Range` .

Alternatives

Doing nothing.

Unresolved questions

None at this point.

Lambda discard parameters

12/28/2021 • 2 minutes to read • [Edit Online](#)

Summary

Allow discards (`_`) to be used as parameters of lambdas and anonymous methods. For example:

- lambdas: `(_, _) => 0`, `(int _, int _) => 0`
- anonymous methods: `delegate(int _, int _) { return 0; }`

Motivation

Unused parameters do not need to be named. The intent of discards is clear, i.e. they are unused/discarded.

Detailed design

Method parameters In the parameter list of a lambda or anonymous method with more than one parameter named `_`, such parameters are discard parameters. Note: if a single parameter is named `_` then it is a regular parameter for backwards compatibility reasons.

Discard parameters do not introduce any names to any scopes. Note this implies they do not cause any `_` (underscore) names to be hidden.

Simple names If `k` is zero and the *simple_name* appears within a *block* and if the *block's* (or an enclosing *block's*) local variable declaration space ([Declarations](#)) contains a local variable, parameter (with the exception of discard parameters) or constant with name `I`, then the *simple_name* refers to that local variable, parameter or constant and is classified as a variable or value.

Scopes With the exception of discard parameters, the scope of a parameter declared in a *lambda_expression* ([Anonymous function expressions](#)) is the *anonymous_function_body* of that *lambda_expression*. With the exception of discard parameters, the scope of a parameter declared in an *anonymous_method_expression* ([Anonymous function expressions](#)) is the *block* of that *anonymous_method_expression*.

Related spec sections

- [Corresponding parameters](#)

Attributes on local functions

12/28/2021 • 2 minutes to read • [Edit Online](#)

Attributes

Local function declarations are now permitted to have [attributes](#). Parameters and type parameters on local functions are also allowed to have attributes.

Attributes with a specified meaning when applied to a method, its parameters, or its type parameters will have the same meaning when applied to a local function, its parameters, or its type parameters, respectively.

A local function can be made conditional in the same sense as a [conditional method](#) by decorating it with a `[ConditionalAttribute]`. A conditional local function must also be `static`. All restrictions on conditional methods also apply to conditional local functions, including that the return type must be `void`.

Extern

The `extern` modifier is now permitted on local functions. This makes the local function external in the same sense as an [external method](#).

Similarly to an external method, the *local-function-body* of an external local function must be a semicolon. A semicolon *local-function-body* is only permitted on an external local function.

An external local function must also be `static`.

Syntax

The [local functions grammar](#) is modified as follows:

```
local-function-header
    : attributes? local-function-modifiers? return-type identifier type-parameter-list?
      ( formal-parameter-list? ) type-parameter-constraints-clauses
    ;

local-function-modifiers
    : (async | unsafe | static | extern)*
    ;

local-function-body
    : block
    | arrow-expression-body
    | ';'
    ;
```

Native-sized integers

12/28/2021 • 10 minutes to read • [Edit Online](#)

Summary

Language support for a native-sized signed and unsigned integer types.

The motivation is for interop scenarios and for low-level libraries.

Design

The identifiers `nint` and `nuint` are new contextual keywords that represent native signed and unsigned integer types. The identifiers are only treated as keywords when name lookup does not find a viable result at that program location.

```
nint x = 3;
string y = nameof(nuint);
_ = nint.Equals(x, 3);
```

The types `nint` and `nuint` are represented by the underlying types `System.IntPtr` and `System.UIntPtr` with compiler surfacing additional conversions and operations for those types as native ints.

Constants

Constant expressions may be of type `nint` or `nuint`. There is no direct syntax for native int literals. Implicit or explicit casts of other integral constant values can be used instead: `const nint i = (nint)42;`

`nint` constants are in the range [`int.MinValue`, `int.MaxValue`].

`nuint` constants are in the range [`uint.MinValue`, `uint.MaxValue`].

There are no `MinValue` or `MaxValue` fields on `nint` or `nuint` because, other than `nuint.MinValue`, those values cannot be emitted as constants.

Constant folding is supported for all unary operators { `+`, `-`, `~` } and binary operators { `+`, `-`, `*`, `/`, `%`, `==`, `!=`, `<`, `<=`, `>`, `>=`, `&`, `|`, `^`, `<<`, `>>` }. Constant folding operations are evaluated with `Int32` and `UInt32` operands rather than native ints for consistent behavior regardless of compiler platform. If the operation results in a constant value in 32-bits, constant folding is performed at compile-time. Otherwise the operation is executed at runtime and not considered a constant.

Conversions

There is an identity conversion between `nint` and `IntPtr`, and between `nuint` and `UIntPtr`. There is an identity conversion between compound types that differ by native ints and underlying types only: arrays, `Nullable<>`, constructed types, and tuples.

The tables below cover the conversions between special types. (The IL for each conversion includes the variants for `unchecked` and `checked` contexts if different.)

OPERAND	TARGET	CONVERSION	IL

OPERAND	TARGET	CONVERSION	IL
<code>nuint</code>	Enumeration	ExplicitEnumeration	

Conversion from `A` to `Nullable` is:

- an implicit nullable conversion if there is an identity conversion or implicit conversion from `A` to `B`;
- an explicit nullable conversion if there is an explicit conversion from `A` to `B`;
- otherwise invalid.

Conversion from `Nullable<A>` to `B` is:

- an explicit nullable conversion if there is an identity conversion or implicit or explicit numeric conversion from `A` to `B`;
- otherwise invalid.

Conversion from `Nullable<A>` to `Nullable` is:

- an identity conversion if there is an identity conversion from `A` to `B`;
- an explicit nullable conversion if there is an implicit or explicit numeric conversion from `A` to `B`;
- otherwise invalid.

Operators

The predefined operators are as follows. These operators are considered during overload resolution based on normal rules for implicit conversions *if at least one of the operands is of type `nint` or `nuint`*.

(The IL for each operator includes the variants for `unchecked` and `checked` contexts if different.)

UNARY	OPERATOR SIGNATURE	IL
<code>+</code>	<code>nint operator +(nint value)</code>	<code>nop</code>
<code>+</code>	<code>nuint operator +(nuint value)</code>	<code>nop</code>
<code>-</code>	<code>nint operator -(nint value)</code>	<code>neg</code>
<code>~</code>	<code>nint operator ~(nint value)</code>	<code>not</code>
<code>~</code>	<code>nuint operator ~(nuint value)</code>	<code>not</code>

BINARY	OPERATOR SIGNATURE	IL
<code>+</code>	<code>nint operator +(nint left, nint right)</code>	<code>add</code> / <code>add.ovf</code>
<code>+</code>	<code>nuint operator +(nuint left, nuint right)</code>	<code>add</code> / <code>add.ovf.un</code>
<code>-</code>	<code>nint operator -(nint left, nint right)</code>	<code>sub</code> / <code>sub.ovf</code>
<code>-</code>	<code>nuint operator -(nuint left, nuint right)</code>	<code>sub</code> / <code>sub.ovf.un</code>

BINARY	OPERATOR SIGNATURE	IL
<code>*</code>	<code>nint operator *(nint left, nint right)</code>	<code>mul</code> / <code>mul.ovf</code>
<code>*</code>	<code>nuint operator *(nuint left, nuint right)</code>	<code>mul</code> / <code>mul.ovf.un</code>
<code>/</code>	<code>nint operator /(nint left, nint right)</code>	<code>div</code>
<code>/</code>	<code>nuint operator /(nuint left, nuint right)</code>	<code>div.un</code>
<code>%</code>	<code>nint operator %(nint left, nint right)</code>	<code>rem</code>
<code>%</code>	<code>nuint operator %(nuint left, nuint right)</code>	<code>rem.un</code>
<code>==</code>	<code>bool operator ==(nint left, nint right)</code>	<code>beq</code> / <code>ceq</code>
<code>==</code>	<code>bool operator ==(nuint left, nuint right)</code>	<code>beq</code> / <code>ceq</code>
<code>!=</code>	<code>bool operator !=(nint left, nint right)</code>	<code>bne</code>
<code>!=</code>	<code>bool operator !=(nuint left, nuint right)</code>	<code>bne</code>
<code><</code>	<code>bool operator <(nint left, nint right)</code>	<code>blt</code> / <code>clt</code>
<code><</code>	<code>bool operator <(nuint left, nuint right)</code>	<code>blt.un</code> / <code>clt.un</code>
<code><=</code>	<code>bool operator <=(nint left, nint right)</code>	<code>ble</code>
<code><=</code>	<code>bool operator <=(nuint left, nuint right)</code>	<code>ble.un</code>
<code>></code>	<code>bool operator >(nint left, nint right)</code>	<code>bgt</code> / <code>cgt</code>
<code>></code>	<code>bool operator >(nuint left, nuint right)</code>	<code>bgt.un</code> / <code>cgt.un</code>
<code>>=</code>	<code>bool operator >=(nint left, nint right)</code>	<code>bge</code>
<code>>=</code>	<code>bool operator >=(nuint left, nuint right)</code>	<code>bge.un</code>
<code>&</code>	<code>nint operator &(nint left, nint right)</code>	<code>and</code>

BINARY	OPERATOR SIGNATURE	IL
<code>&</code>	<code>nuint operator &(nuint left, nuint right)</code>	<code>and</code>
<code> </code>	<code>nint operator (nint left, nint right)</code>	<code>or</code>
<code> </code>	<code>nuint operator (nuint left, nuint right)</code>	<code>or</code>
<code>^</code>	<code>nint operator ^(nint left, nint right)</code>	<code>xor</code>
<code>^</code>	<code>nuint operator ^(nuint left, nuint right)</code>	<code>xor</code>
<code><<</code>	<code>nint operator <<(nint left, int right)</code>	<code>shl</code>
<code><<</code>	<code>nuint operator <<(nuint left, int right)</code>	<code>shl</code>
<code>>></code>	<code>nint operator >>(nint left, int right)</code>	<code>shr</code>
<code>>></code>	<code>nuint operator >>(nuint left, int right)</code>	<code>shr.un</code>

For some binary operators, the IL operators support additional operand types (see [ECMA-335](#) III.1.5 Operand type table). But the set of operand types supported by C# is limited for simplicity and for consistency with existing operators in the language.

Lifted versions of the operators, where the arguments and return types are `nint?` and `nuint?`, are supported.

Compound assignment operations `x op= y` where `x` or `y` are native ints follow the same rules as with other primitive types with pre-defined operators. Specifically the expression is bound as `x = (T)(x op y)` where `T` is the type of `x` and where `x` is only evaluated once.

The shift operators should mask the number of bits to shift - to 5 bits if `sizeof(nint)` is 4, and to 6 bits if `sizeof(nint)` is 8. (see [shift operators](#) in C# spec).

The C#9 compiler will report errors binding to predefined native integer operators when compiling with an earlier language version, but will allow use of predefined conversions to and from native integers.

```
csc -langversion:9 -t:library A.cs
```

```
public class A
{
    public static nint F;
}
```

```
csc -langversion:8 -r:A.dll B.cs
```

```
class B : A
{
    static void Main()
    {
        F = F + 1; // error: nint operator+ not available with -langversion:8
        F = (System.IntPtr)F + 1; // ok
    }
}
```

Dynamic

The conversions and operators are synthesized by the compiler and are not part of the underlying `IntPtr` and `UIntPtr` types. As a result those conversions and operators *are not available* from the runtime binder for `dynamic`.

```
nint x = 2;
nint y = x + x; // ok
dynamic d = x;
nint z = d + x; // RuntimeBinderException: '+' cannot be applied 'System.IntPtr' and 'System.IntPtr'
```

Type members

The only constructor for `nint` or `uint` is the parameter-less constructor.

The following members of `System.IntPtr` and `System.UIntPtr` *are explicitly excluded* from `nint` or `uint`:

```
// constructors
// arithmetic operators
// implicit and explicit conversions
public static readonly IntPtr Zero; // use 0 instead
public static int Size { get; } // use sizeof() instead
public static IntPtr Add(IntPtr pointer, int offset);
public static IntPtr Subtract(IntPtr pointer, int offset);
public int ToInt32();
public long ToInt64();
public void* ToPointer();
```

The remaining members of `System.IntPtr` and `System.UIntPtr` *are implicitly included* in `nint` and `uint`. For .NET Framework 4.7.2:

```
public override bool Equals(object obj);
public override int GetHashCode();
public override string ToString();
public string ToString(string format);
```

Interfaces implemented by `System.IntPtr` and `System.UIntPtr` *are implicitly included* in `nint` and `uint`, with occurrences of the underlying types replaced by the corresponding native integer types. For instance if `IntPtr` implements `ISerializable`, `IEquatable<IntPtr>`, `IComparable<IntPtr>`, then `nint` implements `ISerializable`, `IEquatable<nint>`, `IComparable<nint>`.

Overriding, hiding, and implementing

`nint` and `System.IntPtr`, and `uint` and `System.UIntPtr`, are considered equivalent for overriding, hiding, and implementing.

Overloads cannot differ by `nint` and `System.IntPtr`, and `uint` and `System.UIntPtr`, alone. Overrides and implementations may differ by `nint` and `System.IntPtr`, or `uint` and `System.UIntPtr`, alone. Methods hide other methods that differ by `nint` and `System.IntPtr`, or `uint` and `System.UIntPtr`, alone.

Miscellaneous

`nint` and `nuint` expressions used as array indices are emitted without conversion.

```
static object GetItem(object[] array, nint index)
{
    return array[index]; // ok
}
```

`nint` and `nuint` can be used as an `enum` base type.

```
enum E : nint // ok
{
}
```

Reads and writes are atomic for types `nint`, `nuint`, and `enum` with base type `nint` or `nuint`.

Fields may be marked `volatile` for types `nint` and `nuint`. [ECMA-334](#) 15.5.4 does not include `enum` with base type `System.IntPtr` or `System.UIntPtr` however.

`default(nint)` and `new nint()` are equivalent to `(nint)0`.

`typeof(nint)` is `typeof(IntPtr)`.

`sizeof(nint)` is supported but requires compiling in an unsafe context (as does `sizeof(IntPtr)`). The value is not a compile-time constant. `sizeof(nint)` is implemented as `sizeof(IntPtr)` rather than `IntPtr.Size`.

Compiler diagnostics for type references involving `nint` or `nuint` report `nint` or `nuint` rather than `IntPtr` or `UIntPtr`.

Metadata

`nint` and `nuint` are represented in metadata as `System.IntPtr` and `System.UIntPtr`.

Type references that include `nint` or `nuint` are emitted with a `System.Runtime.CompilerServices.NativeIntegerAttribute` to indicate which parts of the type reference are native ints.

```

namespace System.Runtime.CompilerServices
{
    [AttributeUsage(
        AttributeTargets.Class |
        AttributeTargets.Event |
        AttributeTargets.Field |
        AttributeTargets.GenericParameter |
        AttributeTargets.Parameter |
        AttributeTargets.Property |
        AttributeTargets.ReturnValue,
        AllowMultiple = false,
        Inherited = false)]
    public sealed class NativeIntegerAttribute : Attribute
    {
        public NativeIntegerAttribute()
        {
            TransformFlags = new[] { true };
        }
        public NativeIntegerAttribute(bool[] flags)
        {
            TransformFlags = flags;
        }
        public readonly bool[] TransformFlags;
    }
}

```

The encoding of type references with `NativeIntegerAttribute` is covered in [NativeIntegerAttribute.md](#).

Alternatives

An alternative to the "type erasure" approach above is to introduce new types: `System.NativeInt` and `System.NativeUInt`.

```

public readonly struct NativeInt
{
    public IntPtr Value;
}

```

Distinct types would allow overloading distinct from `IntPtr` and would allow distinct parsing and `ToString()`. But there would be more work for the CLR to handle these types efficiently which defeats the primary purpose of the feature - efficiency. And interop with existing native int code that uses `IntPtr` would be more difficult.

Another alternative is to add more native int support for `IntPtr` in the framework but without any specific compiler support. Any new conversions and arithmetic operations would be supported by the compiler automatically. But the language would not provide keywords, constants, or `checked` operations.

Function Pointers

12/28/2021 • 22 minutes to read • [Edit Online](#)

Summary

This proposal provides language constructs that expose IL opcodes that cannot currently be accessed efficiently, or at all, in C# today: `ldftn` and `calli`. These IL opcodes can be important in high performance code and developers need an efficient way to access them.

Motivation

The motivations and background for this feature are described in the following issue (as is a potential implementation of the feature):

<https://github.com/dotnet/csharplang/issues/191>

This is an alternate design proposal to [compiler intrinsics](#)

Detailed Design

Function pointers

The language will allow for the declaration of function pointers using the `delegate*` syntax. The full syntax is described in detail in the next section but it is meant to resemble the syntax used by `Func` and `Action` type declarations.

```
unsafe class Example {
    void Example(Action<int> a, delegate*<int, void> f) {
        a(42);
        f(42);
    }
}
```

These types are represented using the function pointer type as outlined in ECMA-335. This means invocation of a `delegate*` will use `calli` where invocation of a `delegate` will use `callvirt` on the `Invoke` method. Syntactically though invocation is identical for both constructs.

The ECMA-335 definition of method pointers includes the calling convention as part of the type signature (section 7.1). The default calling convention will be `managed`. Unmanaged calling conventions can be specified by putting an `unmanaged` keyword after the `delegate*` syntax, which will use the runtime platform default. Specific unmanaged conventions can then be specified in brackets to the `unmanaged` keyword by specifying any type starting with `CallConv` in the `System.Runtime.CompilerServices` namespace, leaving off the `CallConv` prefix. These types must come from the program's core library, and the set of valid combinations is platform-dependent.

```
//This method has a managed calling convention. This is the same as leaving the managed keyword off.
delegate* managed<int, int>;

// This method will be invoked using whatever the default unmanaged calling convention on the runtime
// platform is. This is platform and architecture dependent and is determined by the CLR at runtime.
delegate* unmanaged<int, int>;

// This method will be invoked using the cdecl calling convention
// Cdecl maps to System.Runtime.CompilerServices.CallConvCdecl
delegate* unmanaged[Cdecl] <int, int>;

// This method will be invoked using the stdcall calling convention, and suppresses GC transition
// Stdcall maps to System.Runtime.CompilerServices.CallConvStdcall
// SuppressGCTransition maps to System.Runtime.CompilerServices.CallConvSuppressGCTransition
delegate* unmanaged[Stdcall, SuppressGCTransition] <int, int>;
```

Conversions between `delegate*` types is done based on their signature including the calling convention.

```
unsafe class Example {
    void Conversions() {
        delegate*<int, int, int> p1 = ...;
        delegate* managed<int, int, int> p2 = ...;
        delegate* unmanaged<int, int, int> p3 = ...;

        p1 = p2; // okay p1 and p2 have compatible signatures
        Console.WriteLine(p2 == p1); // True
        p2 = p3; // error: calling conventions are incompatible
    }
}
```

A `delegate*` type is a pointer type which means it has all of the capabilities and restrictions of a standard pointer type:

- Only valid in an `unsafe` context.
- Methods which contain a `delegate*` parameter or return type can only be called from an `unsafe` context.
- Cannot be converted to `object`.
- Cannot be used as a generic argument.
- Can implicitly convert `delegate*` to `void*`.
- Can explicitly convert from `void*` to `delegate*`.

Restrictions:

- Custom attributes cannot be applied to a `delegate*` or any of its elements.
- A `delegate*` parameter cannot be marked as `params`.
- A `delegate*` type has all of the restrictions of a normal pointer type.
- Pointer arithmetic cannot be performed directly on function pointer types.

Function pointer syntax

The full function pointer syntax is represented by the following grammar:

```

pointer_type
: ...
| funcptr_type
;

funcptr_type
: 'delegate' '*' calling_convention_specifier? '<' funcptr_parameter_list funcptr_return_type '>'
;

calling_convention_specifier
: 'managed'
| 'unmanaged' ('[' unmanaged_calling_convention ']')?
;

unmanaged_calling_convention
: 'Cdecl'
| 'Stdcall'
| 'Thiscall'
| 'Fastcall'
| identifier (',' identifier)*
;

funcptr_parameter_list
: (funcptr_parameter ',' )*
;

funcptr_parameter
: funcptr_parameter_modifier? type
;

funcptr_return_type
: funcptr_return_modifier? return_type
;

funcptr_parameter_modifier
: 'ref'
| 'out'
| 'in'
;

funcptr_return_modifier
: 'ref'
| 'ref readonly'
;

```

If no `calling_convention_specifier` is provided, the default is `managed`. The precise metadata encoding of the `calling_convention_specifier` and what `identifier`s are valid in the `unmanaged_calling_convention` is covered in [Metadata Representation of Calling Conventions](#).

```

delegate int Func1(string s);
delegate Func1 Func2(Func1 f);

// Function pointer equivalent without calling convention
delegate* <string, int>;
delegate* <delegate* <string, int>, delegate* <string, int>>;

// Function pointer equivalent with calling convention
delegate* managed <string, int>;
delegate* <delegate* managed <string, int>, delegate* <string, int>>;

```

Function pointer conversions

In an unsafe context, the set of available implicit conversions (Implicit conversions) is extended to include the following implicit pointer conversions:

- *Existing conversions*

- From *funcptr_type* `F0` to another *funcptr_type* `F1`, provided all of the following are true:
 - `F0` and `F1` have the same number of parameters, and each parameter `D0n` in `F0` has the same `ref`, `out`, or `in` modifiers as the corresponding parameter `D1n` in `F1`.
 - For each value parameter (a parameter with no `ref`, `out`, or `in` modifier), an identity conversion, implicit reference conversion, or implicit pointer conversion exists from the parameter type in `F0` to the corresponding parameter type in `F1`.
 - For each `ref`, `out`, or `in` parameter, the parameter type in `F0` is the same as the corresponding parameter type in `F1`.
 - If the return type is by value (no `ref` or `ref readonly`), an identity, implicit reference, or implicit pointer conversion exists from the return type of `F1` to the return type of `F0`.
 - If the return type is by reference (`ref` or `ref readonly`), the return type and `ref` modifiers of `F1` are the same as the return type and `ref` modifiers of `F0`.
 - The calling convention of `F0` is the same as the calling convention of `F1`.

Allow address-of to target methods

Method groups will now be allowed as arguments to an address-of expression. The type of such an expression will be a `delegate*` which has the equivalent signature of the target method and a managed calling convention:

```
unsafe class Util {
    public static void Log() { }

    void Use() {
        delegate*<void> ptr1 = &Util.Log;

        // Error: type "delegate*<void>" not compatible with "delegate*<int>";
        delegate*<int> ptr2 = &Util.Log;
    }
}
```

In an unsafe context, a method `M` is compatible with a function pointer type `F` if all of the following are true:

- `M` and `F` have the same number of parameters, and each parameter in `M` has the same `ref`, `out`, or `in` modifiers as the corresponding parameter in `F`.
- For each value parameter (a parameter with no `ref`, `out`, or `in` modifier), an identity conversion, implicit reference conversion, or implicit pointer conversion exists from the parameter type in `M` to the corresponding parameter type in `F`.
- For each `ref`, `out`, or `in` parameter, the parameter type in `M` is the same as the corresponding parameter type in `F`.
- If the return type is by value (no `ref` or `ref readonly`), an identity, implicit reference, or implicit pointer conversion exists from the return type of `F` to the return type of `M`.
- If the return type is by reference (`ref` or `ref readonly`), the return type and `ref` modifiers of `F` are the same as the return type and `ref` modifiers of `M`.
- The calling convention of `M` is the same as the calling convention of `F`. This includes both the calling convention bit, as well as any calling convention flags specified in the unmanaged identifier.
- `M` is a static method.

In an unsafe context, an implicit conversion exists from an address-of expression whose target is a method group `E` to a compatible function pointer type `F` if `E` contains at least one method that is applicable in its normal form to an argument list constructed by use of the parameter types and modifiers of `F`, as described in the following.

- A single method `M` is selected corresponding to a method invocation of the form `E(A)` with the following modifications:
 - The arguments list `A` is a list of expressions, each classified as a variable and with the type and modifier (`ref`, `out`, or `in`) of the corresponding *funcptr_parameter_list* of `F`.
 - The candidate methods are only those methods that are applicable in their normal form, not those applicable in their expanded form.
 - The candidate methods are only those methods that are static.
- If the algorithm of overload resolution produces an error, then a compile-time error occurs. Otherwise, the algorithm produces a single best method `M` having the same number of parameters as `F` and the conversion is considered to exist.
- The selected method `M` must be compatible (as defined above) with the function pointer type `F`. Otherwise, a compile-time error occurs.
- The result of the conversion is a function pointer of type `F`.

This means developers can depend on overload resolution rules to work in conjunction with the address-of operator:

```
unsafe class Util {
    public static void Log() { }
    public static void Log(string p1) { }
    public static void Log(int i) { };

    void Use() {
        delegate*<void> a1 = &Log; // Log()
        delegate*<int, void> a2 = &Log; // Log(int i)

        // Error: ambiguous conversion from method group Log to "void*"
        void* v = &Log;
    }
}
```

The address-of operator will be implemented using the `ldftn` instruction.

Restrictions of this feature:

- Only applies to methods marked as `static`.
- Non-`static` local functions cannot be used in `&`. The implementation details of these methods are deliberately not specified by the language. This includes whether they are static vs. instance or exactly what signature they are emitted with.

Operators on Function Pointer Types

The section in unsafe code on operators is modified as such:

In an unsafe context, several constructs are available for operating on all `_pointer_type_s` that are not `_funcptr_type_s`:

- The `*` operator may be used to perform pointer indirection ([Pointer indirection](#)).
- The `->` operator may be used to access a member of a struct through a pointer ([Pointer member access](#)).
- The `[]` operator may be used to index a pointer ([Pointer element access](#)).
- The `&` operator may be used to obtain the address of a variable ([The address-of operator](#)).
- The `++` and `--` operators may be used to increment and decrement pointers ([Pointer increment and decrement](#)).
- The `+` and `-` operators may be used to perform pointer arithmetic ([Pointer arithmetic](#)).
- The `==`, `!=`, `<`, `>`, `<=`, and `=>` operators may be used to compare pointers ([Pointer comparison](#)).

- The `stackalloc` operator may be used to allocate memory from the call stack ([Fixed size buffers](#)).
- The `fixed` statement may be used to temporarily fix a variable so its address can be obtained ([The fixed statement](#)).

In an unsafe context, several constructs are available for operating on all `_funcptr_type_s`:

- The `&` operator may be used to obtain the address of static methods ([Allow address-of to target methods](#)).
- The `==`, `!=`, `<`, `>`, `<=`, and `=>` operators may be used to compare pointers ([Pointer comparison](#)).

Additionally, we modify all the sections in `Pointers in expressions` to forbid function pointer types, except `Pointer comparison` and `The sizeof operator`.

Better function member

The better function member specification will be changed to include the following line:

A `delegate*` is more specific than `void*`

This means that it is possible to overload on `void*` and a `delegate*` and still sensibly use the address-of operator.

Type Inference

In unsafe code, the following changes are made to the type inference algorithms:

Input types

<https://github.com/dotnet/csharpplang/blob/master/spec/expressions.md#input-types>

The following is added:

If `E` is an address-of method group and `T` is a function pointer type then all the parameter types of `T` are input types of `E` with type `T`.

Output types

<https://github.com/dotnet/csharpplang/blob/master/spec/expressions.md#output-types>

The following is added:

If `E` is an address-of method group and `T` is a function pointer type then the return type of `T` is an output type of `E` with type `T`.

Output type inferences

<https://github.com/dotnet/csharpplang/blob/master/spec/expressions.md#output-type-inferences>

The following bullet is added between bullets 2 and 3:

- If `E` is an address-of method group and `T` is a function pointer type with parameter types `T1...Tk` and return type `Tb`, and overload resolution of `E` with the types `T1...Tk` yields a single method with return type `U`, then a *lower-bound inference* is made from `U` to `Tb`.

Exact inferences

<https://github.com/dotnet/csharpplang/blob/master/spec/expressions.md#exact-inferences>

The following sub-bullet is added as a case to bullet 2:

- `V` is a function pointer type `delegate*<V2...Vk, V1>` and `U` is a function pointer type

`delegate*<U2..Uk, U1>` , and the calling convention of `v` is identical to `u` , and the refness of `vi` is identical to `ui` .

Lower-bound inferences

<https://github.com/dotnet/csharpplang/blob/master/spec/expressions.md#lower-bound-inferences>

The following case is added to bullet 3:

- `v` is a function pointer type `delegate*<V2..Vk, V1>` and there is a function pointer type `delegate*<U2..Uk, U1>` such that `u` is identical to `delegate*<U2..Uk, U1>` , and the calling convention of `v` is identical to `u` , and the refness of `vi` is identical to `ui` .

The first bullet of inference from `ui` to `vi` is modified to:

- If `u` is not a function pointer type and `ui` is not known to be a reference type, or if `u` is a function pointer type and `ui` is not known to be a function pointer type or a reference type, then an *exact inference* is made

Then, added after the 3rd bullet of inference from `ui` to `vi` :

- Otherwise, if `v` is `delegate*<V2..Vk, V1>` then inference depends on the i-th parameter of `delegate*<V2..Vk, V1>` :
 - If `V1`:
 - If the return is by value, then a *lower-bound inference* is made.
 - If the return is by reference, then an *exact inference* is made.
 - If `V2..Vk`:
 - If the parameter is by value, then an *upper-bound inference* is made.
 - If the parameter is by reference, then an *exact inference* is made.

Upper-bound inferences

<https://github.com/dotnet/csharpplang/blob/master/spec/expressions.md#upper-bound-inferences>

The following case is added to bullet 2:

- `u` is a function pointer type `delegate*<U2..Uk, U1>` and `v` is a function pointer type which is identical to `delegate*<V2..Vk, V1>` , and the calling convention of `u` is identical to `v` , and the refness of `ui` is identical to `vi` .

The first bullet of inference from `ui` to `vi` is modified to:

- If `u` is not a function pointer type and `ui` is not known to be a reference type, or if `u` is a function pointer type and `ui` is not known to be a function pointer type or a reference type, then an *exact inference* is made

Then added after the 3rd bullet of inference from `ui` to `vi` :

- Otherwise, if `u` is `delegate*<U2..Uk, U1>` then inference depends on the i-th parameter of `delegate*<U2..Uk, U1>` :
 - If `U1`:
 - If the return is by value, then an *upper-bound inference* is made.
 - If the return is by reference, then an *exact inference* is made.

- If U2..Uk:
 - If the parameter is by value, then a *lower-bound inference* is made.
 - If the parameter is by reference, then an *exact inference* is made.

Metadata representation of `in`, `out`, and `ref readonly` parameters and return types

Function pointer signatures have no parameter flags location, so we must encode whether parameters and the return type are `in`, `out`, or `ref readonly` by using modreqs.

`in`

We reuse `System.Runtime.InteropServices.InAttribute`, applied as a `modreq` to the ref specifier on a parameter or return type, to mean the following:

- If applied to a parameter ref specifier, this parameter is treated as `in`.
- If applied to the return type ref specifier, the return type is treated as `ref readonly`.

`out`

We use `System.Runtime.InteropServices.OutAttribute`, applied as a `modreq` to the ref specifier on a parameter type, to mean that the parameter is an `out` parameter.

Errors

- It is an error to apply `outAttribute` as a modreq to a return type.
- It is an error to apply both `InAttribute` and `OutAttribute` as a modreq to a parameter type.
- If either are specified via modopt, they are ignored.

Metadata Representation of Calling Conventions

Calling conventions are encoded in a method signature in metadata by a combination of the `CallKind` flag in the signature and zero or more `modopt`s at the start of the signature. ECMA-335 currently declares the following elements in the `CallKind` flag:

```
CallKind
: default
| unmanaged cdecl
| unmanaged fastcall
| unmanaged thiscall
| unmanaged stdcall
| varargs
;
```

Of these, function pointers in C# will support all but `varargs`.

In addition, the runtime (and eventually 335) will be updated to include a new `CallKind` on new platforms. This does not have a formal name currently, but this document will use `unmanaged ext` as a placeholder to stand for the new extensible calling convention format. With no `modopt`s, `unmanaged ext` is the platform default calling convention, `unmanaged` without the square brackets.

Mapping the `calling_convention_specifier` to a `CallKind`

A `calling_convention_specifier` that is omitted, or specified as `managed`, maps to the `default` `CallKind`. This is default `CallKind` of any method not attributed with `UnmanagedCallersOnly`.

C# recognizes 4 special identifiers that map to specific existing unmanaged `CallKind`s from ECMA 335. In order for this mapping to occur, these identifiers must be specified on their own, with no other identifiers, and this

requirement is encoded into the spec for `unmanaged_calling_convention`s. These identifiers are `Cdecl`, `Thiscall`, `Stdcall`, and `Fastcall`, which correspond to `unmanaged cdecl`, `unmanaged thiscall`, `unmanaged stdcall`, and `unmanaged fastcall`, respectively. If more than one `identifier` is specified, or the single `identifier` is not of the specially recognized identifiers, we perform special name lookup on the identifier with the following rules:

- We prepend the `identifier` with the string `CallConv`.
- We look only at types defined in the `System.Runtime.CompilerServices` namespace.
- We look only at types defined in the core library of the application, which is the library that defines `System.Object` and has no dependencies.
- We look only at public types.

If lookup succeeds on all of the `identifier`s specified in an `unmanaged_calling_convention`, we encode the `CallKind` as `unmanaged ext`, and encode each of the resolved types in the set of `modopt`s at the beginning of the function pointer signature. As a note, these rules mean that users cannot prefix these `identifier`s with `CallConv`, as that will result in looking up `CallConvCallConvVectorCall`.

When interpreting metadata, we first look at the `CallKind`. If it is anything other than `unmanaged ext`, we ignore all `modopt`s on the return type for the purposes of determining the calling convention, and use only the `CallKind`. If the `CallKind` is `unmanaged ext`, we look at the `modopts` at the start of the function pointer type, taking the union of all types that meet the following requirements:

- The is defined in the core library, which is the library that references no other libraries and defines `System.Object`.
- The type is defined in the `System.Runtime.CompilerServices` namespace.
- The type starts with the prefix `CallConv`.
- The type is public.

These represent the types that must be found when performing lookup on the `identifier`s in an `unmanaged_calling_convention` when defining a function pointer type in source.

It is an error to attempt to use a function pointer with a `CallKind` of `unmanaged ext` if the target runtime does not support the feature. This will be determined by looking for the presence of the `System.Runtime.CompilerServices.RuntimeFeature.UnmanagedCallKind` constant. If this constant is present, the runtime is considered to support the feature.

`System.Runtime.InteropServices.UnmanagedCallersOnlyAttribute`

`System.Runtime.InteropServices.UnmanagedCallersOnlyAttribute` is an attribute used by the CLR to indicate that a method should be called with a specific calling convention. Because of this, we introduce the following support for working with the attribute:

- It is an error to directly call a method annotated with this attribute from C#. Users must obtain a function pointer to the method and then invoke that pointer.
- It is an error to apply the attribute to anything other than an ordinary static method or ordinary static local function. The C# compiler will mark any non-static or static non-ordinary methods imported from metadata with this attribute as unsupported by the language.
- It is an error for a method marked with the attribute to have a parameter or return type that is not an `unmanaged_type`.
- It is an error for a method marked with the attribute to have type parameters, even if those type parameters are constrained to `unmanaged`.
- It is an error for a method in a generic type to be marked with the attribute.
- It is an error to convert a method marked with the attribute to a delegate type.
- It is an error to specify any types for `UnmanagedCallersOnly.CallConvs` that do not meet the requirements for

calling convention `modopts` in metadata.

When determining the calling convention of a method marked with a valid `UnmanagedCallersOnly` attribute, the compiler performs the following checks on the types specified in the `CallConvs` property to determine the effective `CallKind` and `modopts` that should be used to determine the calling convention:

- If no types are specified, the `CallKind` is treated as `unmanaged_ext`, with no calling convention `modopts` at the start of the function pointer type.
- If there is one type specified, and that type is named `CallConvCdecl`, `CallConvThiscall`, `CallConvStdcall`, or `CallConvFastcall`, the `CallKind` is treated as `unmanaged_cdecl`, `unmanaged_thiscall`, `unmanaged_stdcall`, or `unmanaged_fastcall`, respectively, with no calling convention `modopts` at the start of the function pointer type.
- If multiple types are specified or the single type is not named one of the specially called out types above, the `CallKind` is treated as `unmanaged_ext`, with the union of the types specified treated as `modopts` at the start of the function pointer type.

The compiler then looks at this effective `CallKind` and `modopt` collection and uses normal metadata rules to determine the final calling convention of the function pointer type.

Open Questions

Detecting runtime support for `unmanaged_ext`

<https://github.com/dotnet/runtime/issues/38135> tracks adding this flag. Depending on the feedback from review, we will either use the property specified in the issue, or use the presence of

`UnmanagedCallersOnlyAttribute` as the flag that determines whether the runtimes supports `unmanaged_ext`.

Considerations

Allow instance methods

The proposal could be extended to support instance methods by taking advantage of the `EXPLICITTHIS` CLI calling convention (named `instance` in C# code). This form of CLI function pointers puts the `this` parameter as an explicit first parameter of the function pointer syntax.

```
unsafe class Instance {
    void Use() {
        delegate* instance<Instance, string> f = &ToString;
        f(this);
    }
}
```

This is sound but adds some complication to the proposal. Particularly because function pointers which differed by the calling convention `instance` and `managed` would be incompatible even though both cases are used to invoke managed methods with the same C# signature. Also in every case considered where this would be valuable to have there was a simple work around: use a `static` local function.

```
unsafe class Instance {
    void Use() {
        static string toString(Instance i) => i.ToString();
        delegate*<Instance, string> f = &toString;
        f(this);
    }
}
```

Don't require unsafe at declaration

Instead of requiring `unsafe` at every use of a `delegate*`, only require it at the point where a method group is converted to a `delegate*`. This is where the core safety issues come into play (knowing that the containing assembly cannot be unloaded while the value is alive). Requiring `unsafe` on the other locations can be seen as excessive.

This is how the design was originally intended. But the resulting language rules felt very awkward. It's impossible to hide the fact that this is a pointer value and it kept peeking through even without the `unsafe` keyword. For example the conversion to `object` can't be allowed, it can't be a member of a `class`, etc ... The C# design is to require `unsafe` for all pointer uses and hence this design follows that.

Developers will still be capable of presenting a *safe* wrapper on top of `delegate*` values the same way that they do for normal pointer types today. Consider:

```
unsafe struct Action {
    delegate*<void> _ptr;

    Action(delegate*<void> ptr) => _ptr = ptr;
    public void Invoke() => _ptr();
}
```

Using delegates

Instead of using a new syntax element, `delegate*`, simply use existing `delegate` types with a `*` following the type:

```
Func<object, object, bool>* ptr = &object.ReferenceEquals;
```

Handling calling convention can be done by annotating the `delegate` types with an attribute that specifies a `CallingConvention` value. The lack of an attribute would signify the managed calling convention.

Encoding this in IL is problematic. The underlying value needs to be represented as a pointer yet it also must:

1. Have a unique type to allow for overloads with different function pointer types.
2. Be equivalent for OHI purposes across assembly boundaries.

The last point is particularly problematic. This means that every assembly which uses `Func<int>*` must encode an equivalent type in metadata even though `Func<int>*` is defined in an assembly though doesn't control. Additionally any other type which is defined with the name `System.Func<T>` in an assembly that is not `mscorlib` must be different than the version defined in `mscorlib`.

One option that was explored was emitting such a pointer as `mod_req(Func<int>) void*`. This doesn't work though as a `mod_req` cannot bind to a `TypeSpec` and hence cannot target generic instantiations.

Named function pointers

The function pointer syntax can be cumbersome, particularly in complex cases like nested function pointers. Rather than have developers type out the signature every time the language could allow for named declarations of function pointers as is done with `delegate`.

```
func* void Action();

unsafe class NamedExample {
    void M(Action a) {
        a();
    }
}
```

Part of the problem here is the underlying CLI primitive doesn't have names hence this would be purely a C# invention and require a bit of metadata work to enable. That is doable but is a significant amount of work. It essentially requires C# to have a companion to the type def table purely for these names.

Also when the arguments for named function pointers were examined we found they could apply equally well to a number of other scenarios. For example it would be just as convenient to declare named tuples to reduce the need to type out the full signature in all cases.

```
(int x, int y) Point;

class NamedTupleExample {
    void M(Point p) {
        Console.WriteLine(p.x);
    }
}
```

After discussion we decided to not allow named declaration of `delegate*` types. If we find there is significant need for this based on customer usage feedback then we will investigate a naming solution that works for function pointers, tuples, generics, etc ... This is likely to be similar in form to other suggestions like full `typedef` support in the language.

Future Considerations

static delegates

This refers to [the proposal](#) to allow for the declaration of `delegate` types which can only refer to `static` members. The advantage being that such `delegate` instances can be allocation free and better in performance sensitive scenarios.

If the function pointer feature is implemented the `static delegate` proposal will likely be closed out. The proposed advantage of that feature is the allocation free nature. However recent investigations have found that is not possible to achieve due to assembly unloading. There must be a strong handle from the `static delegate` to the method it refers to in order to keep the assembly from being unloaded out from under it.

To maintain every `static delegate` instance would be required to allocate a new handle which runs counter to the goals of the proposal. There were some designs where the allocation could be amortized to a single allocation per call-site but that was a bit complex and didn't seem worth the trade off.

That means developers essentially have to decide between the following trade offs:

1. Safety in the face of assembly unloading: this requires allocations and hence `delegate` is already a sufficient option.
2. No safety in face of assembly unloading: use a `delegate*`. This can be wrapped in a `struct` to allow usage outside an `unsafe` context in the rest of the code.

Suppress emitting of `localsinit` flag.

12/28/2021 • 3 minutes to read • [Edit Online](#)

Summary

Allow suppressing emit of `localsinit` flag via `SkipLocalsInitAttribute` attribute.

Motivation

Background

Per CLR spec local variables that do not contain references are not initialized to a particular value by the VM/JIT. Reading from such variables without initialization is type-safe, but otherwise the behavior is undefined and implementation specific. Typically uninitialized locals contain whatever values were left in the memory that is now occupied by the stack frame. That could lead to nondeterministic behavior and hard to reproduce bugs.

There are two ways to "assign" a local variable:

- by storing a value or
- by specifying `localsinit` flag which forces everything that is allocated from the local memory pool to be zero-initialized NOTE: this includes both local variables and `stackalloc` data.

Use of uninitialized data is discouraged and is not allowed in verifiable code. While it might be possible to prove that by the means of flow analysis, it is permitted for the verification algorithm to be conservative and simply require that `localsinit` is set.

Historically C# compiler emits `localsinit` flag on all methods that declare locals.

While C# employs definite-assignment analysis which is more strict than what CLR spec would require (C# also needs to consider scoping of locals), it is not strictly guaranteed that the resulting code would be formally verifiable:

- CLR and C# rules may not agree on whether passing a local as `out` argument is a `use`.
- CLR and C# rules may not agree on treatment of conditional branches when conditions are known (constant propagation).
- CLR could as well simply require `localinits`, since that is permitted.

Problem

In high-performance application the cost of forced zero-initialization could be noticeable. It is particularly noticeable when `stackalloc` is used.

In some cases JIT can elide initial zero-initialization of individual locals when such initialization is "killed" by subsequent assignments. Not all JITs do this and such optimization has limits. It does not help with `stackalloc`.

To illustrate that the problem is real - there is a known bug where a method not containing any `IL` locals would not have `localsinit` flag. The bug is already being exploited by users by putting `stackalloc` into such methods - intentionally to avoid initialization costs. That is despite the fact that absence of `IL` locals is an unstable metric and may vary depending on changes in codegen strategy. The bug should be fixed and users should get a more documented and reliable way of suppressing the flag.

Detailed design

Allow specifying `System.Runtime.CompilerServices.SkipLocalsInitAttribute` as a way to tell the compiler to not emit `localsinit` flag.

The end result of this will be that the locals may not be zero-initialized by the JIT, which is in most cases unobservable in C#.

In addition to that `stackalloc` data will not be zero-initialized. That is definitely observable, but also is the most motivating scenario.

Permitted and recognized attribute targets are: `Method`, `Property`, `Module`, `Class`, `Struct`, `Interface`, `Constructor`. However compiler will not require that attribute is defined with the listed targets nor it will care in which assembly the attribute is defined.

When attribute is specified on a container (`class`, `module`, containing method for a nested method, ...), the flag affects all methods contained within the container.

Synthesized methods "inherit" the flag from the logical container/owner.

The flag affects only codegen strategy for actual method bodies. I.E. the flag has no effect on abstract methods and is not propagated to overriding/implementing methods.

This is explicitly a *compiler feature* and *not a language feature*.

Similarly to compiler command line switches the feature controls implementation details of a particular codegen strategy and does not need to be required by the C# spec.

Drawbacks

- Old/other compilers may not honor the attribute. Ignoring the attribute is compatible behavior. Only may result in a slight perf hit.
- The code without `localinits` flag may trigger verification failures. Users that ask for this feature are generally unconcerned with verifiability.
- Applying the attribute at higher levels than an individual method has nonlocal effect, which is observable when `stackalloc` is used. Yet, this is the most requested scenario.

Alternatives

- omit `localinits` flag when method is declared in `unsafe` context. That could cause silent and dangerous behavior change from deterministic to nondeterministic in a case of `stackalloc`.
- omit `localinits` flag always. Even worse than above.
- omit `localinits` flag unless `stackalloc` is used in the method body. Does not address the most requested scenario and may turn code unverifiable with no option to revert that back.

Unresolved questions

- Should the attribute be actually emitted to metadata?

Design meetings

None yet.

Unconstrained type parameter annotations

12/28/2021 • 2 minutes to read • [Edit Online](#)

Summary

Allow nullable annotations for type parameters that are not constrained to value types or reference types: `T?`.

```
static T? FirstOrDefault<T>(this IEnumerable<T> collection) { ... }
```

`?` annotation

In C#8, `?` annotations could only be applied to type parameters that were explicitly constrained to value types or reference types. In C#9, `?` annotations can be applied to any type parameter, regardless of constraints.

Unless a type parameter is explicitly constrained to value types, annotations can only be applied within a `#nullable enable` context.

If a type parameter `T` is substituted with a reference type, then `T?` represents a nullable instance of that reference type.

```
var s1 = new string[0].FirstOrDefault(); // string? s1
var s2 = new string?[0].FirstOrDefault(); // string? s2
```

If `T` is substituted with a value type, then `T?` represents an instance of `T`.

```
var i1 = new int[0].FirstOrDefault(); // int i1
var i2 = new int?[0].FirstOrDefault(); // int? i2
```

If `T` is substituted with an annotated type `U?`, then `T?` represents the annotated type `U?` rather than `U??`.

```
var u1 = new U[0].FirstOrDefault(); // U? u1
var u2 = new U?[0].FirstOrDefault(); // U? u2
```

If `T` is substituted with a type `U`, then `T?` represents `U?`, even within a `#nullable disable` context.

```
#nullable disable
var u3 = new U[0].FirstOrDefault(); // U? u3
```

For return values, `T?` is equivalent to `[MaybeNull]T`; for argument values, `T?` is equivalent to `[AllowNull]T`. The equivalence is important when overriding or implementing interfaces from an assembly compiled with C#8.

```
public abstract class A
{
    [return: MaybeNull] public abstract T F1<T>();
    public abstract void F2<T>([AllowNull] T t);
}

public class B : A
{
    public override T? F1<T>() where T : default { ... } // matches A.F1<T>()
    public override void F2<T>(T? t) where T : default { ... } // matches A.F2<T>()
}
```

default constraint

For compatibility with existing code where overridden and explicitly implemented generic methods could not include explicit constraint clauses, `T?` in an overridden or explicitly implemented method is treated as `Nullable<T>` where `T` is a value type.

To allow annotations for type parameters constrained to reference types, C#8 allowed explicit `where T : class` and `where T : struct` constraints on the overridden or explicitly implemented method.

```
class A1
{
    public virtual void F1<T>(T? t) where T : struct { }
    public virtual void F1<T>(T? t) where T : class { }
}

class B1 : A1
{
    public override void F1<T>(T? t) /*where T : struct*/ { }
    public override void F1<T>(T? t) where T : class { }
}
```

To allow annotations for type parameters that are not constrained to reference types or value types, C#9 allows a new `where T : default` constraint.

```
class A2
{
    public virtual void F2<T>(T? t) where T : struct { }
    public virtual void F2<T>(T? t) { }
}

class B2 : A2
{
    public override void F2<T>(T? t) /*where T : struct*/ { }
    public override void F2<T>(T? t) where T : default { }
}
```

It is an error to use a `default` constraint other than on a method override or explicit implementation. It is an error to use a `default` constraint when the corresponding type parameter in the overridden or interface method is constrained to a reference type or value type.

Record structs

12/28/2021 • 10 minutes to read • [Edit Online](#)

The syntax for a record struct is as follows:

```
record_struct_declaration
    : attributes? struct_modifier* 'partial'? 'record' 'struct' identifier type_parameter_list?
      parameter_list? struct_interfaces? type_parameter_constraints_clause* record_struct_body
    ;

record_struct_body
    : struct_body
    | ';'
    ;
```

Record struct types are value types, like other struct types. They implicitly inherit from the class `System.ValueType`. The modifiers and members of a record struct are subject to the same restrictions as those of structs (accessibility on type, modifiers on members, `base(...)` instance constructor initializers, definite assignment for `this` in constructor, destructors, ...). Record structs will also follow the same rules as structs for parameterless instance constructors and field initializers, but this document assumes that we will lift those restrictions for structs generally.

See <https://github.com/dotnet/csharp-lang/blob/master/spec/structs.md> See [parameterless struct constructors spec](#).

Record structs cannot use `ref` modifier.

At most one partial type declaration of a partial record struct may provide a `parameter_list`. The `parameter_list` may not be empty.

Record struct parameters cannot use `ref`, `out` or `this` modifiers (but `in` and `params` are allowed).

Members of a record struct

In addition to the members declared in the record struct body, a record struct type has additional synthesized members. Members are synthesized unless a member with a "matching" signature is declared in the record struct body or an accessible concrete non-virtual member with a "matching" signature is inherited. Two members are considered matching if they have the same signature or would be considered "hiding" in an inheritance scenario. See <https://github.com/dotnet/csharp-lang/blob/master/spec/basic-concepts.md#signatures-and-overloading>

It is an error for a member of a record struct to be named "Clone".

It is an error for an instance field of a record struct to have an unsafe type.

A record struct is not permitted to declare a destructor.

The synthesized members are as follows:

Equality members

The synthesized equality members are similar as in a record class (`Equals` for this type, `Equals` for `object` type, `==` and `!=` operators for this type), except for the lack of `EqualityContract`, null checks or inheritance.

The record struct implements `System.IEquatable<R>` and includes a synthesized strongly-typed overload of `Equals(R other)` where `R` is the record struct. The method is `public`. The method can be declared explicitly. It is an error if the explicit declaration does not match the expected signature or accessibility.

If `Equals(R other)` is user-defined (not synthesized) but `GetHashCode` is not, a warning is produced.

```
public readonly bool Equals(R other);
```

The synthesized `Equals(R)` returns `true` if and only if for each instance field `fieldN` in the record struct the value of `System.Collections.Generic.EqualityComparer<TN>.Default.Equals(fieldN, other.fieldN)` where `TN` is the field type is `true`.

The record struct includes synthesized `==` and `!=` operators equivalent to operators declared as follows:

```
public static bool operator==(R r1, R r2)
    => r1.Equals(r2);
public static bool operator!=(R r1, R r2)
    => !(r1 == r2);
```

The `Equals` method called by the `==` operator is the `Equals(R other)` method specified above. The `!=` operator delegates to the `==` operator. It is an error if the operators are declared explicitly.

The record struct includes a synthesized override equivalent to a method declared as follows:

```
public override readonly bool Equals(object? obj);
```

It is an error if the override is declared explicitly. The synthesized override returns `other is R temp && Equals(temp)` where `R` is the record struct.

The record struct includes a synthesized override equivalent to a method declared as follows:

```
public override readonly int GetHashCode();
```

The method can be declared explicitly.

A warning is reported if one of `Equals(R)` and `GetHashCode()` is explicitly declared but the other method is not explicit.

The synthesized override of `GetHashCode()` returns an `int` result of combining the values of `System.Collections.Generic.EqualityComparer<TN>.Default.GetHashCode(fieldN)` for each instance field `fieldN` with `TN` being the type of `fieldN`.

For example, consider the following record struct:

```
record struct R1(T1 P1, T2 P2);
```

For this record struct, the synthesized equality members would be something like:

```

struct R1 : IEquatable<R1>
{
    public T1 P1 { get; set; }
    public T2 P2 { get; set; }
    public override bool Equals(object? obj) => obj is R1 temp && Equals(temp);
    public bool Equals(R1 other)
    {
        return
            EqualityComparer<T1>.Default.Equals(P1, other.P1) &&
            EqualityComparer<T2>.Default.Equals(P2, other.P2);
    }
    public static bool operator==(R1 r1, R1 r2)
        => r1.Equals(r2);
    public static bool operator!=(R1 r1, R1 r2)
        => !(r1 == r2);
    public override int GetHashCode()
    {
        return Combine(
            EqualityComparer<T1>.Default.GetHashCode(P1),
            EqualityComparer<T2>.Default.GetHashCode(P2));
    }
}

```

Printing members: PrintMembers and ToString methods

The record struct includes a synthesized method equivalent to a method declared as follows:

```
private bool PrintMembers(System.Text.StringBuilder builder);
```

The method does the following:

1. for each of the record struct's printable members (non-static public field and readable property members), appends that member's name followed by " = " followed by the member's value separated with ", ",
2. return true if the record struct has printable members.

For a member that has a value type, we will convert its value to a string representation using the most efficient method available to the target platform. At present that means calling `ToString` before passing to `StringBuilder.Append`.

If the record's printable members do not include a readable property with a non-`readonly` `get` accessor, then the synthesized `PrintMembers` is `readonly`. There is no requirement for the record's fields to be `readonly` for the `PrintMembers` method to be `readonly`.

The `PrintMembers` method can be declared explicitly. It is an error if the explicit declaration does not match the expected signature or accessibility.

The record struct includes a synthesized method equivalent to a method declared as follows:

```
public override string ToString();
```

If the record struct's `PrintMembers` method is `readonly`, then the synthesized `ToString()` method is `readonly`.

The method can be declared explicitly. It is an error if the explicit declaration does not match the expected signature or accessibility.

The synthesized method:

1. creates a `StringBuilder` instance,
2. appends the record struct name to the builder, followed by " { ",

- invokes the record struct's `PrintMembers` method giving it the builder, followed by `" "` if it returned true,
- appends `"}`",
- returns the builder's contents with `builder.ToString()`.

For example, consider the following record struct:

```
record struct R1(T1 P1, T2 P2);
```

For this record struct, the synthesized printing members would be something like:

```
struct R1 : IEquatable<R1>
{
    public T1 P1 { get; set; }
    public T2 P2 { get; set; }

    private bool PrintMembers(StringBuilder builder)
    {
        builder.Append(nameof(P1));
        builder.Append(" = ");
        builder.Append(this.P1); // or builder.Append(this.P1.ToString()); if P1 has a value type
        builder.Append(", ");

        builder.Append(nameof(P2));
        builder.Append(" = ");
        builder.Append(this.P2); // or builder.Append(this.P2.ToString()); if P2 has a value type

        return true;
    }

    public override string ToString()
    {
        var builder = new StringBuilder();
        builder.Append(nameof(R1));
        builder.Append(" { ");

        if (PrintMembers(builder))
            builder.Append(" ");

        builder.Append("}");
        return builder.ToString();
    }
}
```

Positional record struct members

In addition to the above members, record structs with a parameter list ("positional records") synthesize additional members with the same conditions as the members above.

Primary Constructor

A record struct has a public constructor whose signature corresponds to the value parameters of the type declaration. This is called the primary constructor for the type. It is an error to have a primary constructor and a constructor with the same signature already present in the struct.

Instance field declarations for a record struct are permitted to include variable initializers. If there is no primary constructor, the instance initializers execute as part of the parameterless constructor. Otherwise, at runtime the primary constructor executes the instance initializers appearing in the record-struct-body.

If a record struct has a primary constructor, any user-defined constructor must have an explicit `this` constructor initializer that calls the primary constructor or an explicitly declared constructor.

Parameters of the primary constructor as well as members of the record struct are in scope within initializers of instance fields or properties. Instance members would be an error in these locations (similar to how instance members are in scope in regular constructor initializers today, but an error to use), but the parameters of the primary constructor would be in scope and useable and would shadow members. Static members would also be useable.

A warning is produced if a parameter of the primary constructor is not read.

The definite assignment rules for struct instance constructors apply to the primary constructor of record structs. For instance, the following is an error:

```
record struct Pos(int X) // definite assignment error in primary constructor
{
    private int x;
    public int X { get { return x; } set { x = value; } } = X;
}
```

Properties

For each record struct parameter of a record struct declaration there is a corresponding public property member whose name and type are taken from the value parameter declaration.

For a record struct:

- A public `get` and `init` auto-property is created if the record struct has `readonly` modifier, `get` and `set` otherwise. Both kinds of set accessors (`set` and `init`) are considered "matching". So the user may declare an init-only property in place of a synthesized mutable one. An inherited `abstract` property with matching type is overridden. No auto-property is created if the record struct has an instance field with expected name and type. It is an error if the inherited property does not have `public` `get` and `set` / `init` accessors. It is an error if the inherited property or field is hidden.

The auto-property is initialized to the value of the corresponding primary constructor parameter. Attributes can be applied to the synthesized auto-property and its backing field by using `property:` or `field:` targets for attributes syntactically applied to the corresponding record struct parameter.

Deconstruct

A positional record struct with at least one parameter synthesizes a public void-returning instance method called `Deconstruct` with an out parameter declaration for each parameter of the primary constructor declaration. Each parameter of the `Deconstruct` method has the same type as the corresponding parameter of the primary constructor declaration. The body of the method assigns each parameter of the `Deconstruct` method to the value from an instance member access to a member of the same name. If the instance members accessed in the body do not include a property with a non-`readonly` `get` accessor, then the synthesized `Deconstruct` method is `readonly`. The method can be declared explicitly. It is an error if the explicit declaration does not match the expected signature or accessibility, or is static.

Allow `with` expression on structs

It is now valid for the receiver in a `with` expression to have a struct type.

On the right hand side of the `with` expression is a `member_initializer_list` with a sequence of assignments to *identifier*, which must be an accessible instance field or property of the receiver's type.

For a receiver with struct type, the receiver is first copied, then each `member_initializer` is processed the same way as an assignment to a field or property access of the result of the conversion. Assignments are processed in lexical order.

Improvements on records

Allow `record class`

The existing syntax for record types allows `record class` with the same meaning as `record`:

```
record_declaration
: attributes? class_modifier* 'partial'? 'record' 'class'? identifier type_parameter_list?
  parameter_list? record_base? type_parameter_constraints_clause* record_body
;
```

Allow user-defined positional members to be fields

See <https://github.com/dotnet/csharplang/blob/master/meetings/2020/LDM-2020-10-05.md#changing-the-member-type-of-a-primary-constructor-parameter>

No auto-property is created if the record has or inherits an instance field with expected name and type.

Allow parameterless constructors and member initializers in structs

See [parameterless struct constructors](#) spec.

Open questions

- how to recognize record structs in metadata? (we don't have an unspeakable clone method to leverage...)

Answered

- confirm that we want to keep PrintMembers design (separate method returning `bool`) (answer: yes)
- confirm we won't allow `record ref struct` (issue with `IEquatable<RefStruct>` and ref fields) (answer: yes)
- confirm implementation of equality members. Alternative is that synthesized `bool Equals(R other)`, `bool Equals(object? other)` and operators all just delegate to `ValueType.Equals`. (answer: yes)
- confirm that we want to allow field initializers when there is a primary constructor. Do we also want to allow parameterless struct constructors while we're at it (the Activator issue was apparently fixed)? (answer: yes, updated spec should be reviewed in LDM)
- how much do we want to say about `Combine` method? (answer: as little as possible)
- should we disallow a user-defined constructor with a copy constructor signature? (answer: no, there is no notion of copy constructor in the record structs spec)
- confirm that we want to disallow members named "Clone". (answer: correct)
- double-check that synthesized `Equals` logic is functionally equivalent to runtime implementation (e.g. `float.NaN`) (answer: confirmed in LDM)
- could field- or property-targeting attributes be placed in the positional parameter list? (answer: yes, same as for record class)
- `with` on generics? (answer: out of scope for C# 10)
- should `GetHashCode` include a hash of the type itself, to get different values between `record struct S1;` and `record struct S2;`? (answer: no)

Parameterless struct constructors

12/28/2021 • 6 minutes to read • [Edit Online](#)

Summary

Support parameterless constructors and instance field initializers for struct types.

Motivation

Explicit parameterless constructors would give more control over minimally constructed instances of the struct type. Instance field initializers would allow simplified initialization across multiple constructors. Together these would close an obvious gap between `struct` and `class` declarations.

Support for field initializers would also allow initialization of fields in `record struct` declarations without explicitly implementing the primary constructor.

```
record struct Person(string Name)
{
    public object Id { get; init; } = GetNextId();
}
```

If struct field initializers are supported for constructors with parameters, it seems natural to extend that to parameterless constructors as well.

```
record struct Person()
{
    public string Name { get; init; }
    public object Id { get; init; } = GetNextId();
}
```

Proposal

Instance field initializers

Instance field declarations for a struct may include initializers.

As with [class field initializers](#):

A variable initializer for an instance field cannot reference the instance being created.

Constructors

A struct may declare a parameterless instance constructor.

A parameterless instance constructor is valid for all struct kinds including `struct`, `readonly struct`, `ref struct`, and `record struct`.

If the struct declaration does not contain any explicit instance constructors, and the struct has field initializers, the compiler will synthesize a `public` parameterless instance constructor. The parameterless constructor may be synthesized even if all initializer values are zeros.

Otherwise, the struct (see [struct constructors](#)) ...

implicitly has a parameterless instance constructor which always returns the value that results from setting all value type fields to their default value and all reference type fields to null.

Modifiers

A parameterless instance struct constructor must be declared `public`.

```
struct S0 { } // ok
struct S1 { public S1() { } } // ok
struct S2 { internal S2() { } } // error: parameterless constructor must be 'public'
```

Non-public constructors are ignored when importing types from metadata.

Constructors can be declared `extern` or `unsafe`. Constructors cannot be `partial`.

Executing field initializers

Execution of struct instance field initializers matches execution of [class field initializers](#) with **one** qualifier:

When an instance constructor has no constructor initializer, **or when the constructor initializer `this()` represents the default parameterless constructor**, ... that constructor implicitly performs the initializations specified by the *variable_initializers* of the instance fields This corresponds to a sequence of assignments that are executed immediately upon entry to the constructor The variable initializers are executed in the textual order in which they appear in the ... declaration.

Definite assignment

Instance fields (other than `fixed` fields) must be definitely assigned in struct instance constructors that do not have a `this()` initializer (see [struct constructors](#)).

Definite assignment of struct instance fields is required within synthesized and explicit parameterless constructors.

```
struct S0 // ok: no synthesized constructor
{
    int x;
    object y;
}

struct S1
{
    int x = 1;
    object y; // error: field 'y' must be assigned
}

struct S2
{
    int x = 1;
    object y;
    public S2() { } // error: field 'y' must be assigned
}
```

No `base()` initializer

A `base()` initializer is disallowed in struct constructors.

The compiler will not emit a call to the base `System.ValueType` constructor from any struct instance constructors including explicit and synthesized parameterless constructors.

record struct

If a `record struct` does not contain a primary constructor nor any instance constructors, and the `record struct` has field initializers, the compiler will synthesize a `public` parameterless instance constructor.

```
record struct R0; // no parameterless .ctor
record struct R1 { int F = 42; } // synthesized .ctor: public R1() { F = 42; }
record struct R2(int F) { int F = F; } // no parameterless .ctor
```

A `record struct` with an empty parameter list will have a parameterless primary constructor.

```
record struct R3(); // primary .ctor: public R3() { }
record struct R4() { int F = 42; } // primary .ctor: public R4() { F = 42; }
```

An explicit parameterless constructor in a `record struct` must have a `this` initializer that calls the primary constructor or an explicitly declared constructor.

```
record struct R5(int F)
{
    public R5() { } // error: must have 'this' initializer that calls explicit .ctor
    public R5(object o) : this() { } // ok
    public int F = F;
}
```

Fields

The implicitly-defined parameterless constructor will zero fields rather than calling any parameterless constructors for the field types. No warnings are reported that field constructors are ignored. *No change from C#9.*

```
struct S0
{
    public S0() { }
}

struct S1
{
    S0 F; // S0 constructor ignored
}

struct S<T> where T : struct
{
    T F; // constructor (if any) ignored
}
```

`default` **expression**

`default` ignores the parameterless constructor and generates a zeroed instance. *No change from C#9.*

```
// struct S { public S() { } }

_ = default(S); // constructor ignored, no warning
```

`new()`

Object creation invokes the parameterless constructor if public; otherwise the instance is zeroed. *No change from C#9.*

```
// public struct PublicConstructor { public PublicConstructor() { } }
// public struct PrivateConstructor { private PrivateConstructor() { } }

_ = new PublicConstructor(); // call PublicConstructor::.ctor()
_ = new PrivateConstructor(); // initobj PrivateConstructor
```

A warning wave may report a warning for use of `new()` with a struct type that has constructors but no parameterless constructor. No warning will be reported when using substituting such a struct type for a type parameter with a `new()` or `struct` constraint.

```
struct S { public S(int i) { } }
static T CreateNew<T>() where T : new() => new T();

_ = new S(); // warning: no constructor called
_ = CreateNew<S>(); // ok
```

Uninitialized values

A local or field of a struct type that is not explicitly initialized is zeroed. The compiler reports a definite assignment error for an uninitialized struct that is not empty. *No change from C#9.*

```
NoConstructor s1;
PublicConstructor s2;
s1.ToString(); // error: use of unassigned local (unless type is empty)
s2.ToString(); // error: use of unassigned local (unless type is empty)
```

Array allocation

Array allocation ignores any parameterless constructor and generates zeroed elements. *No change from C#9.*

```
// struct S { public S() { } }

var a = new S[1]; // constructor ignored, no warning
```

Parameter default value `new()`

A parameter default value of `new()` binds to the parameterless constructor if public (and reports an error that the value is not constant); otherwise the instance is zeroed. *No change from C#9.*

```
// public struct PublicConstructor { public PublicConstructor() { } }
// public struct PrivateConstructor { private PrivateConstructor() { } }

static void F1(PublicConstructor s1 = new()) { } // error: default value must be constant
static void F2(PrivateConstructor s2 = new()) { } // ok: initobj
```

Type parameter constraints: `new()` and `struct`

The `new()` and `struct` type parameter constraints require the parameterless constructor to be `public` if defined (see [satisfying constraints](#)).

The compiler assumes all structs satisfy `new()` and `struct` constraints. *No change from C#9.*

```
// public struct PublicConstructor { public PublicConstructor() { } }
// public struct InternalConstructor { internal InternalConstructor() { } }

static T CreateNew<T>() where T : new() => new T();
static T CreateStruct<T>() where T : struct => new T();

_ = CreateNew<PublicConstructor>(); // ok
_ = CreateStruct<PublicConstructor>(); // ok

_ = CreateNew<InternalConstructor>(); // compiles; may fail at runtime
_ = CreateStruct<InternalConstructor>(); // compiles; may fail at runtime
```

`new T()` is emitted as a call to `System.Activator.CreateInstance<T>()`, and the compiler assumes the implementation of `CreateInstance<T>()` invokes the `public` parameterless constructor if defined.

With .NET Framework, `Activator.CreateInstance<T>()` invokes the parameterless constructor if the constraint is `where T : new()` but appears to ignore the parameterless constructor if the constraint is `where T : struct`.

Optional parameters

Constructors with optional parameters are not considered parameterless constructors. *No change from C#9.*

```
struct S1 { public S1(string s = "") { } }
struct S2 { public S2(params object[] args) { } }

_ = new S1(); // ok: ignores constructor
_ = new S2(); // ok: ignores constructor
```

Metadata

Explicit and synthesized parameterless struct instance constructors will be emitted to metadata.

Public parameterless struct instance constructors will be imported from metadata; non-public struct instance constructors will be ignored. *No change from C#9.*

Global Using Directive

12/28/2021 • 13 minutes to read • [Edit Online](#)

Syntax for a using directive is extended with an optional `global` keyword that can precede the `using` keyword:

```
compilation_unit
    : extern_alias_directive* global_using_directive* using_directive* global_attributes?
  namespace_member_declaration*
    ;

global_using_directive
    : global_using_alias_directive
    | global_using_namespace_directive
    | global_using_static_directive
    ;

global_using_alias_directive
    : 'global' 'using' identifier '=' namespace_or_type_name ';'
    ;

global_using_namespace_directive
    : 'global' 'using' namespace_name ';'
    ;

global_using_static_directive
    : 'global' 'using' 'static' type_name ';'
    ;
```

- The *global_using_directives* are allowed only on the Compilation Unit level (cannot be used inside a *namespace_declaration*).
- The *global_using_directives*, if any, must precede any *using_directives*.
- The scope of a *global_using_directives* extends over the *namespace_member_declarations* of all compilation units within the program. The scope of a *global_using_directive* specifically does not include other *global_using_directives*. Thus, peer *global_using_directives* or those from a different compilation unit do not affect each other, and the order in which they are written is insignificant. The scope of a *global_using_directive* specifically does not include *using_directives* immediately contained in any compilation unit of the program.

The effect of adding a *global_using_directive* to a program can be thought of as the effect of adding a similar *using_directive* that resolves to the same target namespace or type to every compilation unit of the program. However, the target of a *global_using_directive* is resolved in context of the compilation unit that contains it.

Scopes

<https://github.com/dotnet/csharp-lang/blob/master/spec/basic-concepts.md#scopes>

These are the relevant bullet points with proposed additions (which are in **bold**):

- The scope of name defined by an *extern_alias_directive* extends over the ***global_using_directives***, *using_directives*, *global_attributes* and *namespace_member_declarations* of its immediately containing compilation unit or namespace body. An *extern_alias_directive* does not contribute any new members to the underlying declaration space. In other words, an *extern_alias_directive* is not transitive, but, rather, affects only the compilation unit or namespace body in which it occurs.
- The scope of a name defined or imported by a ***global_using_directive*** extends over the

global_attributes and *namespace_member_declarations* of all the *compilation_units* in the program.

Namespace and type names

<https://github.com/dotnet/csharpplang/blob/master/spec/basic-concepts.md#namespace-and-type-names>

Changes are made to the algorithm determining the meaning of a *namespace_or_type_name* as follows.

This is the relevant bullet point with proposed additions (which are in **bold**):

- If the *namespace_or_type_name* is of the form **I** or of the form **I<A1, ..., Ak>**:
 - If **K** is zero and the *namespace_or_type_name* appears within a generic method declaration (**Methods**) and if that declaration includes a type parameter (**Type parameters**) with name **I**, then the *namespace_or_type_name* refers to that type parameter.
 - Otherwise, if the *namespace_or_type_name* appears within a type declaration, then for each instance type **T** (**The instance type**), starting with the instance type of that type declaration and continuing with the instance type of each enclosing class or struct declaration (if any):
 - If **K** is zero and the declaration of **T** includes a type parameter with name **I**, then the *namespace_or_type_name* refers to that type parameter.
 - Otherwise, if the *namespace_or_type_name* appears within the body of the type declaration, and **T** or any of its base types contain a nested accessible type having name **I** and **K** type parameters, then the *namespace_or_type_name* refers to that type constructed with the given type arguments. If there is more than one such type, the type declared within the more derived type is selected. Note that non-type members (constants, fields, methods, properties, indexers, operators, instance constructors, destructors, and static constructors) and type members with a different number of type parameters are ignored when determining the meaning of the *namespace_or_type_name*.
 - If the previous steps were unsuccessful then, for each namespace **N**, starting with the namespace in which the *namespace_or_type_name* occurs, continuing with each enclosing namespace (if any), and ending with the global namespace, the following steps are evaluated until an entity is located:
 - If **K** is zero and **I** is the name of a namespace in **N**, then:
 - If the location where the *namespace_or_type_name* occurs is enclosed by a namespace declaration for **N** and the namespace declaration contains an *extern_alias_directive* or *using_alias_directive* that associates the name **I** with a namespace or type, **or any namespace declaration for N in the program contains a *global_using_alias_directive* that associates the name I with a namespace or type**, then the *namespace_or_type_name* is ambiguous and a compile-time error occurs.
 - Otherwise, the *namespace_or_type_name* refers to the namespace named **I** in **N**.
 - Otherwise, if **N** contains an accessible type having name **I** and **K** type parameters, then:
 - If **K** is zero and the location where the *namespace_or_type_name* occurs is enclosed by a namespace declaration for **N** and the namespace declaration contains an *extern_alias_directive* or *using_alias_directive* that associates the name **I** with a namespace or type, **or any namespace declaration for N in the program contains a *global_using_alias_directive* that associates the name I with a namespace or type**, then the *namespace_or_type_name* is ambiguous and a compile-time error occurs.
 - Otherwise, the *namespace_or_type_name* refers to the type constructed with the given type arguments.
 - Otherwise, if the location where the *namespace_or_type_name* occurs is enclosed by a namespace declaration for **N**:

- If `K` is zero and the namespace declaration contains an *extern_alias_directive* or *using_alias_directive* that associates the name `I` with an imported namespace or type, **or any namespace declaration for `N` in the program contains a *global_using_alias_directive* that associates the name `I` with an imported namespace or type**, then the *namespace_or_type_name* refers to that namespace or type.
- Otherwise, if the namespaces and type declarations imported by the *using_namespace_directives* and *using_alias_directives* of the namespace declaration **and the namespaces and type declarations imported by the *global_using_namespace_directives* and *global_using_static_directives* of any namespace declaration for `N` in the program** contain exactly one accessible type having name `I` and `K` type parameters, then the *namespace_or_type_name* refers to that type constructed with the given type arguments.
- Otherwise, if the namespaces and type declarations imported by the *using_namespace_directives* and *using_alias_directives* of the namespace declaration **and the namespaces and type declarations imported by the *global_using_namespace_directives* and *global_using_static_directives* of any namespace declaration for `N` in the program** contain more than one accessible type having name `I` and `K` type parameters, then the *namespace_or_type_name* is ambiguous and an error occurs.
- Otherwise, the *namespace_or_type_name* is undefined and a compile-time error occurs.

Simple names

<https://github.com/dotnet/csharp-lang/blob/master/spec/expressions.md#simple-names>

Changes are made to the *simple_name* evaluation rules as follows.

This is the relevant bullet point with proposed additions (which are **in bold**):

- Otherwise, for each namespace `N`, starting with the namespace in which the *simple_name* occurs, continuing with each enclosing namespace (if any), and ending with the global namespace, the following steps are evaluated until an entity is located:
 - If `K` is zero and `I` is the name of a namespace in `N`, then:
 - If the location where the *simple_name* occurs is enclosed by a namespace declaration for `N` and the namespace declaration contains an *extern_alias_directive* or *using_alias_directive* that associates the name `I` with a namespace or type, **or any namespace declaration for `N` in the program contains a *global_using_alias_directive* that associates the name `I` with a namespace or type**, then the *simple_name* is ambiguous and a compile-time error occurs.
 - Otherwise, the *simple_name* refers to the namespace named `I` in `N`.
 - Otherwise, if `N` contains an accessible type having name `I` and `K` type parameters, then:
 - If `K` is zero and the location where the *simple_name* occurs is enclosed by a namespace declaration for `N` and the namespace declaration contains an *extern_alias_directive* or *using_alias_directive* that associates the name `I` with a namespace or type, **or any namespace declaration for `N` in the program contains a *global_using_alias_directive* that associates the name `I` with a namespace or type**, then the *simple_name* is ambiguous and a compile-time error occurs.
 - Otherwise, the *namespace_or_type_name* refers to the type constructed with the given type arguments.
 - Otherwise, if the location where the *simple_name* occurs is enclosed by a namespace declaration for

N :

- If **K** is zero and the namespace declaration contains an *extern_alias_directive* or *using_alias_directive* that associates the name **I** with an imported namespace or type, or **any namespace declaration for N in the program contains a global_using_alias_directive** that associates the name **I** with an imported namespace or type, then the *simple_name* refers to that namespace or type.
- Otherwise, if the namespaces and type declarations imported by the *using_namespace_directives* and *using_static_directives* of the namespace declaration **and the namespaces and type declarations imported by the global_using_namespace_directives and global_using_static_directives of any namespace declaration for N in the program** contain exactly one accessible type or non-extension static member having name **I** and **K** type parameters, then the *simple_name* refers to that type or member constructed with the given type arguments.
- Otherwise, if the namespaces and types imported by the *using_namespace_directives* of the namespace declaration **and the namespaces and type declarations imported by the global_using_namespace_directives and global_using_static_directives of any namespace declaration for N in the program** contain more than one accessible type or non-extension-method static member having name **I** and **K** type parameters, then the *simple_name* is ambiguous and an error occurs.

Extension method invocations

<https://github.com/dotnet/csharpplang/blob/master/spec/expressions.md#extension-method-invocations>

Changes are made to the algorithm to find the best *type_name* **C** as follows. This is the relevant bullet point with proposed additions (which are in **bold**):

- Starting with the closest enclosing namespace declaration, continuing with each enclosing namespace declaration, and ending with the containing compilation unit, successive attempts are made to find a candidate set of extension methods:
 - If the given namespace or compilation unit directly contains non-generic type declarations **C_i** with eligible extension methods **M_j**, then the set of those extension methods is the candidate set.
 - If types **C_i** imported by *using_static_declarations* and directly declared in namespaces imported by *using_namespace_directives* in the given namespace or compilation unit **and, if containing compilation unit is reached, imported by global_using_static_declarations and directly declared in namespaces imported by global_using_namespace_directives in the program** directly contain eligible extension methods **M_j**, then the set of those extension methods is the candidate set.

Compilation units

<https://github.com/dotnet/csharpplang/blob/master/spec/namespaces.md#compilation-units>

A *compilation_unit* defines the overall structure of a source file. A compilation unit consists of **zero or more global_using_directives followed by zero or more using_directives followed by zero or more global_attributes followed by zero or more namespace_member_declarations**.

```
compilation_unit
: extern_alias_directive* global_using_directive* using_directive* global_attributes?
namespace_member_declaration*
;
```

A C# program consists of one or more compilation units, each contained in a separate source file. When a C#

program is compiled, all of the compilation units are processed together. Thus, compilation units can depend on each other, possibly in a circular fashion.

The *global_using_directives* of a compilation unit affect the *global_attributes* and *namespace_member_declarations* of all compilation units in the program.

Extern aliases

<https://github.com/dotnet/csharplang/blob/master/spec/namespaces.md#extern-aliases>

The scope of an *extern_alias_directive* extends over the *global_using_directives*, *using_directives*, *global_attributes* and *namespace_member_declarations* of its immediately containing compilation unit or namespace body.

Using alias directives

<https://github.com/dotnet/csharplang/blob/main/spec/namespaces.md#using-alias-directives>

The order in which *using_alias_directives* are written has no significance, and resolution of the *namespace_or_type_name* referenced by a *using_alias_directive* is not affected by the *using_alias_directive* itself or by other *using_directives* in the immediately containing compilation unit or namespace body, **and, if the *using_alias_directive* is immediately contained in a compilation unit, is not affected by the *global_using_directives* in the program.** In other words, the *namespace_or_type_name* of a *using_alias_directive* is resolved as if the immediately containing compilation unit or namespace body had no *using_directives* and, **if the *using_alias_directive* is immediately contained in a compilation unit, the program had no *global_using_directives*.** A *using_alias_directive* may however be affected by *extern_alias_directives* in the immediately containing compilation unit or namespace body.

Global Using alias directives

A *global_using_alias_directive* introduces an identifier that serves as an alias for a namespace or type within the program.

```
global_using_alias_directive
: 'global' 'using' identifier '=' namespace_or_type_name ';'
;
```

Within member declarations in any compilation unit of a program that contains a *global_using_alias_directive*, the identifier introduced by the *global_using_alias_directive* can be used to reference the given namespace or type.

The *identifier* of a *global_using_alias_directive* must be unique within the declaration space of any compilation unit of a program that contains the *global_using_alias_directive*.

Just like regular members, names introduced by *global_using_alias_directives* are hidden by similarly named members in nested scopes.

The order in which *global_using_alias_directives* are written has no significance, and resolution of the *namespace_or_type_name* referenced by a *global_using_alias_directive* is not affected by the *global_using_alias_directive* itself or by other *global_using_directives* or *using_directives* in the program. In other words, the *namespace_or_type_name* of a *global_using_alias_directive* is resolved as if the immediately containing compilation unit had no *using_directives* and the entire containing program had no *global_using_directives*. A *global_using_alias_directive* may however be affected by *extern_alias_directives* in the immediately containing compilation unit.

A *global_using_alias_directive* can create an alias for any namespace or type.

Accessing a namespace or type through an alias yields exactly the same result as accessing that namespace or type through its declared name.

Using aliases can name a closed constructed type, but cannot name an unbound generic type declaration without supplying type arguments.

Global Using namespace directives

A *global_using_namespace_directive* imports the types contained in a namespace into the program, enabling the identifier of each type to be used without qualification.

```
global_using_namespace_directive
: 'global' 'using' namespace_name ';'
;
```

Within member declarations in a program that contains a *global_using_namespace_directive*, the types contained in the given namespace can be referenced directly.

A *global_using_namespace_directive* imports the types contained in the given namespace, but specifically does not import nested namespaces.

Unlike a *global_using_alias_directive*, a *global_using_namespace_directive* may import types whose identifiers are already defined within a compilation unit of the program. In effect, in a given compilation unit, names imported by any *global_using_namespace_directive* in the program are hidden by similarly named members in the compilation unit.

When more than one namespace or type imported by *global_using_namespace_directives* or *global_using_static_directives* in the same program contain types by the same name, references to that name as a *type_name* are considered ambiguous.

Furthermore, when more than one namespace or type imported by *global_using_namespace_directives* or *global_using_static_directives* in the same program contain types or members by the same name, references to that name as a *simple_name* are considered ambiguous.

The *namespace_name* referenced by a *global_using_namespace_directive* is resolved in the same way as the *namespace_or_type_name* referenced by a *global_using_alias_directive*. Thus, *global_using_namespace_directives* in the same program do not affect each other and can be written in any order.

Global Using static directives

A *global_using_static_directive* imports the nested types and static members contained directly in a type declaration into the containing program, enabling the identifier of each member and type to be used without qualification.

```
global_using_static_directive
: 'global' 'using' 'static' type_name ';'
;
```

Within member declarations in a program that contains a *global_using_static_directive*, the accessible nested types and static members (except extension methods) contained directly in the declaration of the given type can be referenced directly.

A *global_using_static_directive* specifically does not import extension methods directly as static methods, but makes them available for extension method invocation.

A *global_using_static_directive* only imports members and types declared directly in the given type, not members and types declared in base classes.

Ambiguities between multiple *global_using_namespace_directives* and *global_using_static_directives* are discussed in the section for *global_using_namespace_directives* (above).

Namespace alias qualifiers

<https://github.com/dotnet/csharplang/blob/master/spec/namespaces.md#namespace-alias-qualifiers>

Changes are made to the algorithm determining the meaning of a *qualified_alias_member* as follows.

This is the relevant bullet point with proposed additions (which are in **bold**):

- Otherwise, starting with the namespace declaration ([Namespace declarations](#)) immediately containing the *qualified_alias_member* (if any), continuing with each enclosing namespace declaration (if any), and ending with the compilation unit containing the *qualified_alias_member*, the following steps are evaluated until an entity is located:
 - If the namespace declaration or compilation unit contains a *using_alias_directive* that associates N with a type, **or, when a compilation unit is reached, the program contains a *global_using_alias_directive* that associates N with a type**, then the *qualified_alias_member* is undefined and a compile-time error occurs.
 - Otherwise, if the namespace declaration or compilation unit contains an *extern_alias_directive* or *using_alias_directive* that associates N with a namespace, ***or, when a compilation unit is reached, the program contains a *global_using_alias_directive* that associates N with a namespace**, then:
 - If the namespace associated with N contains a namespace named I and K is zero, then the *qualified_alias_member* refers to that namespace.
 - Otherwise, if the namespace associated with N contains a non-generic type named I and K is zero, then the *qualified_alias_member* refers to that type.
 - Otherwise, if the namespace associated with N contains a type named I that has K type parameters, then the *qualified_alias_member* refers to that type constructed with the given type arguments.
 - Otherwise, the *qualified_alias_member* is undefined and a compile-time error occurs.

File Scoped Namespaces

12/28/2021 • 2 minutes to read • [Edit Online](#)

Summary

File scoped namespaces use a less verbose format for the typical case of files containing only one namespace. The file scoped namespace format is `namespace X.Y.Z;` (note the semicolon and lack of braces). This allows for files like the following:

```
namespace X.Y.Z;

using System;

class X
{
}
```

The semantics are that using the `namespace X.Y.Z;` form is equivalent to writing `namespace X.Y.Z { ... }` where the remainder of the file following the file-scoped namespace is in the `...` section of a standard namespace declaration.

Motivation

Analysis of the C# ecosystem shows that approximately 99.7% files are all of either one of these forms:

```
namespace X.Y.Z
{
    // usings

    // types
}
```

or

```
// usings

namespace X.Y.Z
{
    // types
}
```

However, both these forms force the user to indent the majority of their code and add a fair amount of ceremony for what is effectively a very basic concept. This affects clarity, uses horizontal and vertical space, and is often unsatisfying for users both used to C# and coming from other languages (which commonly have less ceremony here).

The primary goal of the feature therefore is to meet the needs of the majority of the ecosystem with less unnecessary boilerplate.

Detailed design

This proposal takes the form of a diff to the existing

<https://github.com/dotnet/csharplang/blob/main/spec/namespaces.md#compilation-units> section of the specification.

Diff

A *compilation_unit* defines the overall structure of a source file. A compilation unit consists of zero or more *using_directives* followed by zero or more *global_attributes* followed by zero or more *namespace_member_declarations*.

A *compilation_unit* defines the overall structure of a source file. A compilation unit consists of zero or more *using_directives* followed by zero or more *global_attributes* followed by a *compilation_unit_body*. A *compilation_unit_body* can either be a *file_scoped_namespace_declaration* or zero or more *statements* and *namespace_member_declarations*.

```
compilation_unit
~~      : extern_alias_directive* using_directive* global_attributes? namespace_member_declaration*~~
      : extern_alias_directive* using_directive* global_attributes? compilation_unit_body
      ;

compilation_unit_body
      : statement* namespace_member_declaration*
      | file_scoped_namespace_declaration
      ;
```

... unchanged ...

A *file_scoped_namespace_declaration* will contribute members corresponding to the *namespace_declaration* it is semantically equivalent to. See ([Namespace Declarations](#)) for more details.

Namespace declarations

A *namespace_declaration* consists of the keyword `namespace`, followed by a namespace name and body, optionally followed by a semicolon. A *file_scoped_namespace_declaration* consists of the keyword `namespace`, followed by a namespace name, a semicolon and an optional list of *extern_alias_directives*, *using_directives* and *type_declarations*.

```
namespace_declaration
      : 'namespace' qualified_identifier namespace_body ';' '?'
      ;

file_scoped_namespace_declaration
      : 'namespace' qualified_identifier ';' extern_alias_directive* using_directive* type_declaration*
      ;

... unchanged ...
```

... unchanged ...

the two namespace declarations above contribute to the same declaration space, in this case declaring two classes with the fully qualified names `N1.N2.A` and `N1.N2.B`. Because the two declarations contribute to the same declaration space, it would have been an error if each contained a declaration of a member with the same name.

A *file_scoped_namespace_declaration* permits a namespace declaration to be written without the `{ ... }` block. For example:

```
extern alias A;
namespace Name;
using B;
class C
{
}
```

is semantically equivalent to

```
extern alias A;
namespace Name
{
    using B;
    class C
    {
    }
}
```

Specifically, a *file_scoped_namespace_declaration* is treated the same as a *namespace_declaration* at the same location in the *compilation_unit* with the same *qualified_identifier*. The *extern_alias_directives*, *using_directives* and *type_declarations* of that *file_scoped_namespace_declaration* act as if they were declared in the same order inside the *namespace_body* of that *namespace_declaration*.

A source file cannot contain both a *file_scoped_namespace_declaration* and a *namespace_declaration*. A source file cannot contain multiple *file_scoped_namespace_declarations*. A *compilation_unit* cannot contain both a *file_scoped_namespace_declaration* and any top level *statements*. *type_declarations* cannot precede a *file_scoped_namespace_declaration*.

Extern aliases

... unchanged ...

Extended property patterns

12/28/2021 • 2 minutes to read • [Edit Online](#)

Summary

Allow property subpatterns to reference nested members, for instance:

```
if (e is MethodCallExpression { Method.Name: "MethodName" })
```

Instead of:

```
if (e is MethodCallExpression { Method: { Name: "MethodName" } })
```

Motivation

When you want to match a child property, nesting another recursive pattern adds too much noise which will hurt readability with no real advantage.

Detailed design

The *property_pattern* syntax is modified as follow:

```
property_pattern
: type? property_pattern_clause simple_designation?
;

property_pattern_clause
: '{' (subpattern (',' subpattern)* ','?)? '}'
;

subpattern
- : identifier ':' pattern
+ : subpattern_name ':' pattern
;

+subpattern_name
+ : identifier
+ | subpattern_name '.' identifier
+ ;
```

The receiver for each name lookup is the type of the previous member $T0$, starting from the *input type* of the *property_pattern*. if T is a nullable type, $T0$ is its underlying type, otherwise $T0$ is equal to T .

For example, a pattern of the form `{ Prop1.Prop2: pattern }` is exactly equivalent to

```
{ Prop1: { Prop2: pattern } }.
```

Note that this will include the null check when T is a nullable value type or a reference type. This null check means that the nested properties available will be the properties of $T0$, not of T .

Repeated member paths are allowed. The compilation of pattern matching can take advantage of common parts of patterns.

Improved Interpolated Strings

12/28/2021 • 28 minutes to read • [Edit Online](#)

Summary

We introduce a new pattern for creating and using interpolated string expressions to allow for efficient formatting and use in both general `string` scenarios and more specialized scenarios such as logging frameworks, without incurring unnecessary allocations from formatting the string in the framework.

Motivation

Today, string interpolation mainly lowers down to a call to `string.Format`. This, while general purpose, can be inefficient for a number of reasons:

1. It boxes any struct arguments, unless the runtime has happened to introduce an overload of `string.Format` that takes exactly the correct types of arguments in exactly the correct order.
 - This ordering is why the runtime is hesitant to introduce generic versions of the method, as it would lead to combinatoric explosion of generic instantiations of a very common method.
2. It has to allocate an array for the arguments in most cases.
3. There is no opportunity to avoid instantiating the instance if it's not needed. Logging frameworks, for example, will recommend avoiding string interpolation because it will cause a string to be realized that may not be needed, depending on the current log-level of the application.
4. It can never use `Span` or other ref struct types today, because ref structs are not allowed as generic type parameters, meaning that if a user wants to avoid copying to intermediate locations they have to manually format strings.

Internally, the runtime has a type called `ValueStringBuilder` to help deal with the first 2 of these scenarios. They pass a stackalloc'd buffer to the builder, repeatedly call `AppendFormat` with every part, and then get a final string out. If the resulting string goes past the bounds of the stack buffer, they can then move to an array on the heap. However, this type is dangerous to expose directly, as incorrect usage could lead to a rented array to be double-disposed, which then will cause all sorts of undefined behavior in the program as two locations think they have sole access to the rented array. This proposal creates a way to use this type safely from native C# code by just writing an interpolated string literal, leaving written code unchanged while improving every interpolated string that a user writes. It also extends this pattern to allow for interpolated strings passed as arguments to other methods to use a handler pattern, defined by receiver of the method, that will allow things like logging frameworks to avoid allocating strings that will never be needed, and giving C# users familiar, convenient interpolation syntax.

Detailed Design

The handler pattern

We introduce a new handler pattern that can represent an interpolated string passed as an argument to a method. The simple English of the pattern is as follows:

When an *interpolated_string_expression* is passed as an argument to a method, we look at the type of the parameter. If the parameter type has a constructor that can be invoked with 2 int parameters, `LiteralLength` and `FormattedCount`, optionally takes additional parameters specified by an attribute on the original parameter, optionally has an out boolean trailing parameter, and the type of the original parameter has instance `AppendLiteral` and `AppendFormatted` methods that can be invoked for every part of the interpolated string, then

we lower the interpolation using that, instead of into a traditional call to `string.Format(formatStr, args)`. A more concrete example is helpful for picturing this:

```
// The handler that will actually "build" the interpolated string"
[InterpolatedStringHandler]
public ref struct TraceLoggerParamsInterpolatedStringHandler
{
    // Storage for the built-up string

    private bool _logLevelEnabled;

    public TraceLoggerParamsInterpolatedStringHandler(int literalLength, int formattedCount, Logger logger,
out bool handlerIsValid)
    {
        if (!logger._logLevelEnabled)
        {
            handlerIsValid = false;
            return;
        }

        handlerIsValid = true;
        _logLevelEnabled = logger.EnabledLevel;
    }

    public void AppendLiteral(string s)
    {
        // Store and format part as required
    }

    public void AppendFormatted<T>(T t)
    {
        // Store and format part as required
    }
}

// The logger class. The user has an instance of this, accesses it via static state, or some other access
// mechanism
public class Logger
{
    // Initialization code omitted
    public LogLevel EnabledLevel;

    public void LogTrace([InterpolatedStringHandlerArguments("")]TraceLoggerParamsInterpolatedStringHandler
handler)
    {
        // Impl of logging
    }
}

Logger logger = GetLogger(LogLevel.Info);

// Given the above definitions, usage looks like this:
var name = "Fred Silberberg";
logger.LogTrace($"{name} will never be printed because info is < trace!");

// This is converted to:
var name = "Fred Silberberg";
var receiverTemp = logger;
var handler = new TraceLoggerParamsInterpolatedStringHandler(literalLength: 47, formattedCount: 1,
receiverTemp, out var handlerIsValid);
if (handlerIsValid)
{
    handler.AppendFormatted(name);
    handler.AppendLiteral(" will never be printed because info is < trace!");
}
receiverTemp.LogTrace(handler);
```

Here, because `TraceLoggerParamsInterpolatedStringHandler` has a constructor with the correct parameters, we say that the interpolated string has an implicit handler conversion to that parameter, and it lowers to the pattern shown above. The specese needed for this is a bit complicated, and is expanded below.

The rest of this proposal will use `Append...` to refer to either of `AppendLiteral` or `AppendFormatted` in cases when both are applicable.

New attributes

The compiler recognizes the `System.Runtime.CompilerServices.InterpolatedStringHandlerAttribute`:

```
using System;
namespace System.Runtime.CompilerServices
{
    [AttributeUsage(AttributeTargets.Class | AttributeTargets.Struct, AllowMultiple = false, Inherited = false)]
    public sealed class InterpolatedStringHandlerAttribute : Attribute
    {
        public InterpolatedStringHandlerAttribute()
        {
        }
    }
}
```

This attribute is used by the compiler to determine if a type is a valid interpolated string handler type.

The compiler also recognizes the `System.Runtime.CompilerServices.InterpolatedStringHandlerArgumentAttribute`:

```
namespace System.Runtime.CompilerServices
{
    [AttributeUsage(AttributeTargets.Parameter, AllowMultiple = false, Inherited = false)]
    public sealed class InterpolatedStringHandlerArgumentAttribute : Attribute
    {
        public InterpolatedHandlerArgumentAttribute(string argument);
        public InterpolatedHandlerArgumentAttribute(params string[] arguments);

        public string[] Arguments { get; }
    }
}
```

This attribute is used on parameters, to inform the compiler how to lower an interpolated string handler pattern used in a parameter position.

Interpolated string handler conversion

Type `T` is said to be an *applicable interpolated string handler type* if it is attributed with `System.Runtime.CompilerServices.InterpolatedStringHandlerAttribute`. There exists an implicit *interpolated string handler conversion* to `T` from an *interpolated string expression*, or an *additive expression* composed entirely of *interpolated string expression_s* and using only `+` operators.

For simplicity in the rest of this speclet, *interpolated string expression* refers to both a simple *interpolated string expression*, and to an *additive expression* composed entirely of *interpolated string expression_s* and using only `+` operators.

Note that this conversion always exists, regardless of whether there will be later errors when actually attempting to lower the interpolation using the handler pattern. This is done to help ensure that there are predictable and useful errors and that runtime behavior doesn't change based on the content of an interpolated string.

Applicable function member adjustments

We adjust the wording of the [applicable function member algorithm](#) as follows (a new sub-bullet is added to each section, in bold):

A function member is said to be an *applicable function member* with respect to an argument list `A` when all of the following are true:

- Each argument in `A` corresponds to a parameter in the function member declaration as described in [Corresponding parameters](#), and any parameter to which no argument corresponds is an optional parameter.
- For each argument in `A`, the parameter passing mode of the argument (i.e., value, `ref`, or `out`) is identical to the parameter passing mode of the corresponding parameter, and
 - for a value parameter or a parameter array, an implicit conversion ([Implicit conversions](#)) exists from the argument to the type of the corresponding parameter, or
 - for a `ref` parameter whose type is a struct type, an implicit *interpolated_string_handler_conversion* exists from the argument to the type of the corresponding parameter, or
 - for a `ref` or `out` parameter, the type of the argument is identical to the type of the corresponding parameter. After all, a `ref` or `out` parameter is an alias for the argument passed.

For a function member that includes a parameter array, if the function member is applicable by the above rules, it is said to be applicable in its *normal form*. If a function member that includes a parameter array is not applicable in its normal form, the function member may instead be applicable in its *expanded form*:

- The expanded form is constructed by replacing the parameter array in the function member declaration with zero or more value parameters of the element type of the parameter array such that the number of arguments in the argument list `A` matches the total number of parameters. If `A` has fewer arguments than the number of fixed parameters in the function member declaration, the expanded form of the function member cannot be constructed and is thus not applicable.
- Otherwise, the expanded form is applicable if for each argument in `A` the parameter passing mode of the argument is identical to the parameter passing mode of the corresponding parameter, and
 - for a fixed value parameter or a value parameter created by the expansion, an implicit conversion ([Implicit conversions](#)) exists from the type of the argument to the type of the corresponding parameter, or
 - for a `ref` parameter whose type is a struct type, an implicit *interpolated_string_handler_conversion* exists from the argument to the type of the corresponding parameter, or
 - for a `ref` or `out` parameter, the type of the argument is identical to the type of the corresponding parameter.

Important note: this means that if there are 2 otherwise equivalent overloads, that only differ by the type of the *applicable_interpolated_string_handler_type*, these overloads will be considered ambiguous. Further, because we do not see through explicit casts, it is possible that there could arise an unresolvable scenario where both applicable overloads use `InterpolatedStringHandlerArguments` and are totally uncalleable without manually performing the handler lowering pattern. We could potentially make changes to the better function member algorithm to resolve this if we so choose, but this scenario unlikely to occur and isn't a priority to address.

Better conversion from expression adjustments

We change the [better conversion from expression](#) section to the following:

Given an implicit conversion `c1` that converts from an expression `E` to a type `T1`, and an implicit conversion `c2` that converts from an expression `E` to a type `T2`, `c1` is a *better conversion* than `c2` if:

1. `E` is a non-constant *interpolated_string_expression*, `c1` is an *implicit_string_handler_conversion*, `T1` is an *applicable_interpolated_string_handler_type*, and `c2` is not an *implicit_string_handler_conversion*, or
2. `E` does not exactly match `T2` and at least one of the following holds:
 - `E` exactly matches `T1` ([Exactly matching Expression](#))
 - `T1` is a better conversion target than `T2` ([Better conversion target](#))

This does mean that there are some potentially non-obvious overload resolution rules, depending on whether the interpolated string in question is a constant-expression or not. For example:

```
void Log(string s) { ... }
void Log(TraceLoggerParamsInterpolatedStringHandler p) { ... }

Log(""); // Calls Log(string s), because "" is a constant expression
Log($"{test}"); // Calls Log(string s), because $"{test}" is a constant expression
Log($"{1}"); // Calls Log(TraceLoggerParamsInterpolatedStringHandler p), because $"{1}" is not a constant expression
```

This is introduced so that things that can simply be emitted as constants do so, and don't incur any overhead, while things that cannot be constant use the handler pattern.

InterpolatedStringHandler and Usage

We introduce a new type in `System.Runtime.CompilerServices`: `DefaultInterpolatedStringHandler`. This is a ref struct with many of the same semantics as `ValueStringBuilder`, intended for direct use by the C# compiler. This struct would look approximately like this:

```
// API Proposal issue: https://github.com/dotnet/runtime/issues/50601
namespace System.Runtime.CompilerServices
{
    [InterpolatedStringHandler]
    public ref struct DefaultInterpolatedStringHandler
    {
        public DefaultInterpolatedStringHandler(int literalLength, int formattedCount);
        public string ToStringAndClear();

        public void AppendLiteral(string value);

        public void AppendFormatted<T>(T value);
        public void AppendFormatted<T>(T value, string? format);
        public void AppendFormatted<T>(T value, int alignment);
        public void AppendFormatted<T>(T value, int alignment, string? format);

        public void AppendFormatted(ReadOnlySpan<char> value);
        public void AppendFormatted(ReadOnlySpan<char> value, int alignment = 0, string? format = null);

        public void AppendFormatted(string? value);
        public void AppendFormatted(string? value, int alignment = 0, string? format = null);

        public void AppendFormatted(object? value, int alignment = 0, string? format = null);
    }
}
```

We make a slight change to the rules for the meaning of an *interpolated_string_expression*:

If the type of an interpolated string is `string` and the type `System.Runtime.CompilerServices.DefaultInterpolatedStringHandler` exists, and the current context supports using that type, the string is lowered using the handler pattern. The final `string` value is then obtained by calling `ToStringAndClear()` on the handler type. Otherwise, if the type of an interpolated string is `System.IFormattable` or `System.FormattableString` [the rest is unchanged]

The "and the current context supports using that type" rule is intentionally vague to give the compiler leeway in optimizing usage of this pattern. The handler type is likely to be a ref struct type, and ref struct types are normally not permitted in async methods. For this particular case, the compiler would be allowed to make use the handler if none of the interpolation holes contain an `await` expression, as we can statically determine that the handler type is safely used without additional complicated analysis because the handler will be dropped after the interpolated string expression is evaluated.

Open Question:

Do we want to instead just make the compiler know about `DefaultInterpolatedStringHandler` and skip the `string.Format` call entirely? It would allow us to hide a method that we don't necessarily want to put in people's faces when they manually call `string.Format`.

Answer: Yes.

Open Question:

Do we want to have handlers for `System.IFormattable` and `System.FormattableString` as well?

Answer: No.

Handler pattern codegen

In this section, method invocation resolution refers to the steps listed [here](#).

Constructor resolution

Given an *applicable_interpolated_string_handler_type* `T` and an *interpolated_string_expression* `i`, method invocation resolution and validation for a valid constructor on `T` is performed as follows:

1. Member lookup for instance constructors is performed on `T`. The resulting method group is called `M`.
2. The argument list `A` is constructed as follows:
 - a. The first two arguments are integer constants, representing the literal length of `i`, and the number of *interpolation* components in `i`, respectively.
 - b. If `i` is used as an argument to some parameter `pi` in method `M1`, and parameter `pi` is attributed with `System.Runtime.CompilerServices.InterpolatedStringHandlerArgumentAttribute`, then for every name `Argx` in the `Arguments` array of that attribute the compiler matches it to a parameter `px` that has the same name. The empty string is matched to the receiver of `M1`.
 - If any `Argx` is not able to be matched to a parameter of `M1`, or an `Argx` requests the receiver of `M1` and `M1` is a static method, an error is produced and no further steps are taken.
 - Otherwise, the type of every resolved `px` is added to the argument list, in the order specified by the `Arguments` array. Each `px` is passed with the same `ref` semantics as is specified in `M1`.
 - c. The final argument is a `bool`, passed as an `out` parameter.
3. Traditional method invocation resolution is performed with method group `M` and argument list `A`. For the purposes of method invocation final validation, the context of `M` is treated as a *member_access* through type `T`.
 - If a single-best constructor `F` was found, the result of overload resolution is `F`.
 - If no applicable constructors were found, step 3 is retried, removing the final `bool` parameter from `A`. If this retry also finds no applicable members, an error is produced and no further steps are taken.
 - If no single-best method was found, the result of overload resolution is ambiguous, an error is produced, and no further steps are taken.
4. Final validation on `F` is performed.
 - If any element of `A` occurred lexically after `i`, an error is produced and no further steps are taken.
 - If any `A` requests the receiver of `F`, and `F` is an indexer being used as an *initializer_target* in a *member_initializer*, then an error is reported and no further steps are taken.

Note: the resolution here intentionally do *not* use the actual expressions passed as other arguments for `Argx` elements. We only consider the types post-conversion. This makes sure that we don't have double-conversion issues, or unexpected cases where a lambda is bound to one delegate type when passed to `M1` and bound to a different delegate type when passed to `M`.

Note: We report an error for indexers uses as member initializers because of the order of evaluation for nested

member initializers. Consider this code snippet:

```
var x1 = new C1 { C2 = { [GetString()] = { A = 2, B = 4 } } };

/* Lowering:
__c1 = new C1();
string argTemp = GetString();
__c1.C2[argTemp][1] = 2;
__c1.C2[argTemp][3] = 4;

Prints:
GetString
get_C2
get_C2
*/

string GetString()
{
    Console.WriteLine("GetString");
    return "";
}

class C1
{
    private C2 c2 = new C2();
    public C2 C2 { get { Console.WriteLine("get_C2"); return c2; } set { } }
}

class C2
{
    public C3 this[string s]
    {
        get => new C3();
        set { }
    }
}

class C3
{
    public int A
    {
        get => 0;
        set { }
    }
    public int B
    {
        get => 0;
        set { }
    }
}
```

The arguments to `__c1.c2[]` are evaluated *before* the receiver of the indexer. While we could come up with a lowering that works for this scenario (either by creating a temp for `__c1.c2` and sharing it across both indexer invocations, or only using it for the first indexer invocation and sharing the argument across both invocations) we think that any lowering would be confusing for what we believe is a pathological scenario. Therefore, we forbid the scenario entirely.

Open-Question:

If we use a constructor instead of `Create`, we'd improve runtime codegen, at the expense of narrowing the pattern a bit.

Answer: We will restrict to constructors for now. We can revisit adding a general `Create` method later if the

scenario arises.

Append... method overload resolution

Given an *applicable_interpolated_string_handler_type* `T` and an *interpolated_string_expression* `i`, overload resolution for a set of valid `Append...` methods on `T` is performed as follows:

1. If there are any *interpolated_regular_string_character* components in `i`:
 - a. Member lookup on `T` with the name `AppendLiteral` is performed. The resulting method group is called `M1`.
 - b. The argument list `A1` is constructed with one value parameter of type `string`.
 - c. Traditional method invocation resolution is performed with method group `M1` and argument list `A1`. For the purposes of method invocation final validation, the context of `M1` is treated as a *member_access* through an instance of `T`.
 - If a single-best method `Fi` is found and no errors were produced, the result of method invocation resolution is `Fi`.
 - Otherwise, an error is reported.
2. For every *interpolation* `ix` component of `i`:
 - a. Member lookup on `T` with the name `AppendFormatted` is performed. The resulting method group is called `Mf`.
 - b. The argument list `Af` is constructed:
 - a. The first parameter is the *expression* of `ix`, passed by value.
 - b. If `ix` directly contains a *constant_expression* component, then an integer value parameter is added, with the name `alignment` specified.
 - c. If `ix` is directly followed by an *interpolation_format*, then a string value parameter is added, with the name `format` specified.
 - c. Traditional method invocation resolution is performed with method group `Mf` and argument list `Af`. For the purposes of method invocation final validation, the context of `Mf` is treated as a *member_access* through an instance of `T`.
 - If a single-best method `Fi` is found, the result of method invocation resolution is `Fi`.
 - Otherwise, an error is reported.
3. Finally, for every `Fi` discovered in steps 1 and 2, final validation is performed:
 - If any `Fi` does not return `bool` by value or `void`, an error is reported.
 - If all `Fi` do not return the same type, an error is reported.

Note that these rules do not permit extension methods for the `Append...` calls. We could consider enabling that if we choose, but this is analogous to the enumerator pattern, where we allow `GetEnumerator` to be an extension method, but not `Current` or `MoveNext()`.

These rules *do* permit default parameters for the `Append...` calls, which will work with things like `CallerLineNumber` or `CallerArgumentExpression` (when supported by the language).

We have separate overload lookup rules for base elements vs interpolation holes because some handlers will want to be able to understand the difference between the components that were interpolated and the components that were part of the base string.

Open Question

Some scenarios, like structured logging, want to be able to provide names for interpolation elements. For example, today a logging call might look like `Log("{name} bought {itemCount} items", name, items.Count);`. The names inside the `{}` provide important structure information for loggers that help with ensuring output is consistent and uniform. Some cases might be able to reuse the `:format` component of an interpolation hole for this, but many loggers already understand format specifiers and have existing behavior for output formatting

based on this info. Is there some syntax we can use to enable putting these named specifiers in?

Some cases may be able to get away with `CallerArgumentExpression`, provided that support does land in C# 10. But for cases that invoke a method/property, that may not be sufficient.

Answer:

While there are some interesting parts to templated strings we could explore in an orthogonal language feature, we don't think a specific syntax here has much benefit over solutions such as using a tuple:

```
($"{("StructuredCategory", myExpression)})".
```

Performing the conversion

Given an *applicable_interpolated_string_handler_type* `T` and an *interpolated_string_expression* `i` that had a valid constructor `Fc` and `Append...` methods `Fa` resolved, lowering for `i` is performed as follows:

1. Any arguments to `Fc` that occur lexically before `i` are evaluated and stored into temporary variables in lexical order. In order to preserve lexical ordering, if `i` occurred as part of a larger expression `e`, any components of `e` that occurred before `i` will be evaluated as well, again in lexical order.
2. `Fc` is called with the length of the interpolated string literal components, the number of *interpolation* holes, any previously evaluated arguments, and a `bool` out argument (if `Fc` was resolved with one as the last parameter). The result is stored into a temporary value `ib`.
 - a. The length of the literal components is calculated after replacing any *open_brace_escape_sequence* with a single `{`, and any *close_brace_escape_sequence* with a single `}`.
3. If `Fc` ended with a `bool` out argument, a check on that `bool` value is generated. If true, the methods in `Fa` will be called. Otherwise, they will not be called.
4. For every `Fax` in `Fa`, `Fax` is called on `ib` with either the current literal component or *interpolation* expression, as appropriate. If `Fax` returns a `bool`, the result is logically anded with all preceding `Fax` calls.
 - a. If `Fax` is a call to `AppendLiteral`, the literal component is unescaped by replacing any *open_brace_escape_sequence* with a single `{`, and any *close_brace_escape_sequence* with a single `}`.
5. The result of the conversion is `ib`.

Again, note that arguments passed to `Fc` and arguments passed to `e` are the same temp. Conversions may occur on top of the temp to convert to a form that `Fc` requires, but for example lambdas cannot be bound to a different delegate type between `Fc` and `e`.

Open Question

This lowering means that subsequent parts of the interpolated string after a false-returning `Append...` call don't get evaluated. This could potentially be very confusing, particularly if the format hole is side-effecting. We could instead evaluate all format holes first, then repeatedly call `Append...` with the results, stopping if it returns false. This would ensure that all expressions get evaluated as one might expect, but we call as few methods as we need to. While the partial evaluation might be desirable for some more advanced cases, it is perhaps non-intuitive for the general case.

Another alternative, if we want to always evaluate all format holes, is to remove the `Append...` version of the API and just do repeated `Format` calls. The handler can track whether it should just be dropping the argument and immediately returning for this version.

Answer: We will have conditional evaluation of the holes.

Open Question

Do we need to dispose of disposable handler types, and wrap calls with try/finally to ensure that `Dispose` is called? For example, the interpolated string handler in the bcl might have a rented array inside it, and if one of

the interpolation holes throws an exception during evaluation, that rented array could be leaked if it wasn't disposed.

Answer: No. handlers can be assigned to locals (such as `MyHandler handler = $"{MyCode()}";`), and the lifetime of such handlers is unclear. Unlike foreach enumerators, where the lifetime is obvious and no user-defined local is created for the enumerator.

Other considerations

Allow `string` types to be convertible to handlers as well

For type author simplicity, we could consider allowing expressions of type `string` to be implicitly-convertible to *applicable_interpolated_string_handler_types*. As proposed today, authors will likely need to overload on both that handler type and regular `string` types, so their users don't have to understand the difference. This may be an annoying and non-obvious overhead, as a `string` expression can be viewed as an interpolation with `expression.Length` prefilled length and 0 holes to be filled.

This would allow new APIs to only expose a handler, without also having to expose a `string`-accepting overload. However, it won't get around the need for changes to better conversion from expression, so while it would work it may be unnecessary overhead.

Answer:

We think that this could end up being confusing, and there's an easy workaround for custom handler types: add a user-defined conversion from string.

Incorporating spans for heap-less strings

`ValueStringBuilder` as it exists today has 2 constructors: one that takes a count, and allocates on the heap eagerly, and one that takes a `Span<char>`. That `Span<char>` is usually a fixed size in the runtime codebase, around 250 elements on average. To truly replace that type, we should consider an extension to this where we also recognize `GetInterpolatedString` methods that take a `Span<char>`, instead of just the count version. However, we see a few potential thorny cases to resolve here:

- We don't want to `stackalloc` repeatedly in a hot loop. If we were to do this extension to the feature, we'd likely want to share the `stackalloc`'d span between loop iterations. We know this is safe, as `Span<T>` is a ref struct that can't be stored on the heap, and users would have to be pretty devious to manage to extract a reference to that `Span` (such as creating a method that accepts such a handler then deliberately retrieving the `Span` from the handler and returning it to the caller). However, allocating ahead of time produces other questions:
 - Should we eagerly `stackalloc`? What if the loop is never entered, or exits before it needs the space?
 - If we don't eagerly `stackalloc`, does that mean we introduce a hidden branch on every loop? Most loops likely won't care about this, but it could affect some tight loops that don't want to pay the cost.
- Some strings can be quite big, and the appropriate amount to `stackalloc` is dependent on a number of factors, including runtime factors. We don't really want the C# compiler and specification to have to determine this ahead of time, so we'd want to resolve <https://github.com/dotnet/runtime/issues/25423> and add an API for the compiler to call in these cases. It also adds more pros and cons to the points from the previous loop, where we don't want to potentially allocate large arrays on the heap many times or before one is needed.

Answer:

This is out of scope for C# 10. We can look at this in general when we look at the more general `params Span<T>` feature.

Non-try version of the API

For simplicity, this spec currently just proposes recognizing a `Append...` method, and things that always

succeed (like `InterpolatedStringHandler`) would always return true from the method. This was done to support partial formatting scenarios where the user wants to stop formatting if an error occurs or if it's unnecessary, such as the logging case, but could potentially introduce a bunch of unnecessary branches in standard interpolated string usage. We could consider an addendum where we use just `FormatX` methods if no `Append...` method is present, but it does present questions about what we do if there's a mix of both `Append...` and `FormatX` calls.

Answer:

We want the non-try version of the API. The proposal has been updated to reflect this.

Passing previous arguments to the handler

There is unfortunate lack of symmetry in the proposal at it currently exists: invoking an extension method in reduced form produces different semantics than invoking the extension method in normal form. This is different from most other locations in the language, where reduced form is just a sugar. We propose adding an attribute to the framework that we will recognize when binding a method, that informs the compiler that certain parameters should be passed to the constructor on the handler. Usage looks like this:

```
namespace System.Runtime.CompilerServices
{
    [AttributeUsage(AttributeTargets.Parameter, AllowMultiple = false, Inherited = false)]
    public sealed class InterpolatedStringHandlerArgumentAttribute : Attribute
    {
        public InterpolatedStringHandlerArgumentAttribute(string argument);
        public InterpolatedStringHandlerArgumentAttribute(params string[] arguments);

        public string[] Arguments { get; }
    }
}
```

Usage of this is then:

```

namespace System
{
    public sealed class String
    {
        public static string Format(IFormatProvider? provider,
[InterpolatedStringHandlerArgument("provider")] ref DefaultInterpolatedStringHandler handler);
        ...
    }
}

namespace System.Runtime.CompilerServices
{
    public ref struct DefaultInterpolatedStringHandler
    {
        public DefaultInterpolatedStringHandler(int baseLength, int holeCount, IFormatProvider? provider);
// additional factory
        ...
    }
}

var formatted = string.Format(CultureInfo.InvariantCulture, $"{X} = {Y}");

// Is lowered to

var tmp1 = CultureInfo.InvariantCulture;
var handler = new DefaultInterpolatedStringHandler(3, 2, tmp1);
handler.AppendFormatted(X);
handler.AppendLiteral(" = ");
handler.AppendFormatted(Y);
var formatted = string.Format(tmp1, handler);

```

The questions we need to answer:

1. Do we like this pattern in general?
2. Do we want to allow these arguments to come from after the handler parameter? Some existing patterns in the BCL, such as `Utf8Formatter`, put the value to be formatted *before* the thing needed to format into. To fit in best with these patterns, we'd likely want to allow this, but we need to decide if this out-of-order evaluate is ok.

Answer:

We want to support this. The spec has been updated to reflect this. Arguments will be required to be specified in lexical order at the call site, and if a needed argument to the create method is specified after the interpolated string literal, an error is produced.

`await` usage in interpolation holes

Because `($"{await A()}")` is a valid expression today, we need to rationalize how interpolation holes with `await`. We could solve this with a few rules:

1. If an interpolated string used as a `string`, `IFormattable`, or `FormattableString` has an `await` in an interpolation hole, fall back to old-style formatter.
2. If an interpolated string is subject to an *implicit_string_handler_conversion* and *applicable_interpolated_string_handler_type* is a `ref struct`, `await` is not allowed to be used in the format holes.

Fundamentally, this desugaring could use a `ref struct` in an async method as long as we guarantee that the `ref struct` will not need to be saved to the heap, which should be possible if we forbid `await`s in the interpolation holes.

Alternatively, we could simply make all handler types non-ref structs, including the framework handler for

interpolated strings. This would, however, preclude us from someday recognizing a `Span` version that does not need to allocate any scratch space at all.

Answer:

We will treat interpolated string handlers the same as any other type: this means that if the handler type is a `ref struct` and the current context doesn't allow the usage of `ref structs`, it is illegal to use handler here. The spec around lowering of string literals used as strings is intentionally vague to allow the compiler to decide on what rules it deems appropriate, but for custom handler types they will have to follow the same rules as the rest of the language.

Handlers as ref parameters

Some handlers might want to be passed as `ref` parameters (either `in` or `ref`). Should we allow either? And if so, what will a `ref` handler look like? `ref $" "` is confusing, as you're not actually passing the string by `ref`, you're passing the handler that is created from the `ref` by `ref`, and has similar potential issues with `async` methods.

Answer:

We want to support this. The spec has been updated to reflect this. The rules should reflect the same rules that apply to extension methods on value types.

Interpolated strings through binary expressions and conversions

Because this proposal makes interpolated strings context sensitive, we would like to allow the compiler to treat a binary expression composed entirely of interpolated strings, or an interpolated string subjected to a cast, as an interpolated string literal for the purposes of overload resolution. For example, take the following scenario:

```
struct Handler1
{
    public Handler1(int literalLength, int formattedCount, C c) => ...;
    // AppendX... methods as necessary
}
struct Handler2
{
    public Handler2(int literalLength, int formattedCount, C c) => ...;
    // AppendX... methods as necessary
}

class C
{
    void M(Handler1 handler) => ...;
    void M(Handler2 handler) => ...;
}

c.M($"X"); // Ambiguous between the M overloads
```

This would be ambiguous, necessitating a cast to either `Handler1` or `Handler2` in order to resolve. However, in making that cast, we would potentially throw away the information that there is context from the method receiver, meaning that the cast would fail because there is nothing to fill in the information of `c`. A similar issue arises with binary concatenation of strings: the user could want to format the literal across several lines to avoid line wrapping, but would not be able to because that would no longer be an interpolated string literal convertible to the handler type.

To resolve these cases, we make the following changes:

- An *additive_expression* composed entirely of *interpolated_string_expressions* and using only `+` operators is considered to be an *interpolated_string_literal* for the purposes of conversions and overload resolution. The final interpolated string is created by logically concatenating all individual *interpolated_string_expression* components, from left to right.

- A *cast_expression* or a *relational_expression* with operator `as` whose operand is an *interpolated_string_expressions* is considered an *interpolated_string_expressions* for the purposes of conversions and overload resolution.

Open Questions:

Do we want to do this? We don't do this for `System.FormattableString`, for example, but that can be broken out onto a different line, whereas this can be context-dependent and therefore not able to be broken out into a different line. There are also no overload resolution concerns with `FormattableString` and `IFormattable`.

Answer.

We think that this is a valid use case for additive expressions, but that the cast version is not compelling enough at this time. We can add it later if necessary. The spec has been updated to reflect this decision.

Other use cases

See <https://github.com/dotnet/runtime/issues/50635> for examples of proposed handler APIs using this pattern.

Constant Interpolated Strings

12/28/2021 • 3 minutes to read • [Edit Online](#)

Summary

Enables constants to be generated from interpolated strings of type string constant.

Motivation

The following code is already legal:

```
public class C
{
    const string S1 = "Hello world";
    const string S2 = "Hello" + " " + "World";
    const string S3 = S1 + " Kevin, welcome to the team!";
}
```

However, there have been many community requests to make the following also legal:

```
public class C
{
    const string S1 = $"Hello world";
    const string S2 = $"Hello{" " }World";
    const string S3 = $"{S1} Kevin, welcome to the team!";
}
```

This proposal represents the next logical step for constant string generation, where existing string syntax that works in other situations is made to work for constants.

Detailed design

The following represent the updated specifications for constant expressions under this new proposal. Current specifications from which this was directly based on can be found [here](#).

Constant Expressions

A *constant_expression* is an expression that can be fully evaluated at compile-time.

```
constant_expression
: expression
;
```

A constant expression must be the `null` literal or a value with one of the following types: `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `long`, `ulong`, `char`, `float`, `double`, `decimal`, `bool`, `object`, `string`, or any enumeration type. Only the following constructs are permitted in constant expressions:

- Literals (including the `null` literal).
- References to `const` members of class and struct types.
- References to members of enumeration types.
- References to `const` parameters or local variables
- Parenthesized sub-expressions, which are themselves constant expressions.

- Cast expressions, provided the target type is one of the types listed above.
- `checked` and `unchecked` expressions
- Default value expressions
- Nameof expressions
- The predefined `+`, `-`, `!`, and `~` unary operators.
- The predefined `+`, `-`, `*`, `/`, `%`, `<<`, `>>`, `&`, `|`, `^`, `&&`, `||`, `==`, `!=`, `<`, `>`, `<=`, and `>=` binary operators, provided each operand is of a type listed above.
- The `?:` conditional operator.
- *Interpolated strings `{ }`, provided that all components are constant expressions of type `string` and all interpolated components lack alignment and format specifiers.*

The following conversions are permitted in constant expressions:

- Identity conversions
- Numeric conversions
- Enumeration conversions
- Constant expression conversions
- Implicit and explicit reference conversions, provided that the source of the conversions is a constant expression that evaluates to the null value.

Other conversions including boxing, unboxing and implicit reference conversions of non-null values are not permitted in constant expressions. For example:

```
class C
{
    const object i = 5;           // error: boxing conversion not permitted
    const object str = "hello"; // error: implicit reference conversion
}
```

the initialization of `i` is an error because a boxing conversion is required. The initialization of `str` is an error because an implicit reference conversion from a non-null value is required.

Whenever an expression fulfills the requirements listed above, the expression is evaluated at compile-time. This is true even if the expression is a sub-expression of a larger expression that contains non-constant constructs.

The compile-time evaluation of constant expressions uses the same rules as run-time evaluation of non-constant expressions, except that where run-time evaluation would have thrown an exception, compile-time evaluation causes a compile-time error to occur.

Unless a constant expression is explicitly placed in an `unchecked` context, overflows that occur in integral-type arithmetic operations and conversions during the compile-time evaluation of the expression always cause compile-time errors ([Constant expressions](#)).

Constant expressions occur in the contexts listed below. In these contexts, a compile-time error occurs if an expression cannot be fully evaluated at compile-time.

- Constant declarations ([Constants](#)).
- Enumeration member declarations ([Enum members](#)).
- Default arguments of formal parameter lists ([Method parameters](#))
- `case` labels of a `switch` statement ([The switch statement](#)).
- `goto case` statements ([The goto statement](#)).
- Dimension lengths in an array creation expression ([Array creation expressions](#)) that includes an initializer.
- Attributes ([Attributes](#)).

An implicit constant expression conversion ([Implicit constant expression conversions](#)) permits a constant expression of type `int` to be converted to `sbyte`, `byte`, `short`, `ushort`, `uint`, or `ulong`, provided the value of the constant expression is within the range of the destination type.

Drawbacks

This proposal adds additional complexity to the compiler in exchange for broader applicability of interpolated strings. As these strings are fully evaluated at compile time, the valuable automatic formatting features of interpolated strings are less necessary. Most use cases can be largely replicated through the alternatives below.

Alternatives

The current `+` operator for string concatenation can combine strings in a similar manner to the current proposal.

Unresolved questions

What parts of the design are still undecided?

Design meetings

Lambda improvements

12/28/2021 • 13 minutes to read • [Edit Online](#)

Summary

Proposed changes:

1. Allow lambdas with attributes
2. Allow lambdas with explicit return type
3. Infer a natural delegate type for lambdas and method groups

Motivation

Support for attributes on lambdas would provide parity with methods and local functions.

Support for explicit return types would provide symmetry with lambda parameters where explicit types can be specified. Allowing explicit return types would also provide control over compiler performance in nested lambdas where overload resolution must bind the lambda body currently to determine the signature.

A natural type for lambda expressions and method groups will allow more scenarios where lambdas and method groups may be used without an explicit delegate type, including as initializers in `var` declarations.

Requiring explicit delegate types for lambdas and method groups has been a friction point for customers, and has become an impediment to progress in ASP.NET with recent work on [MapAction](#).

[ASP.NET MapAction](#) without proposed changes (`MapAction()` takes a `System.Delegate` argument):

```
[HttpGet("/")] Todo GetTodo() => new(Id: 0, Name: "Name");
app.MapAction((Func<Todo>)GetTodo);

[HttpPost("/")] Todo PostTodo([FromBody] Todo todo) => todo;
app.MapAction((Func<Todo, Todo>)PostTodo);
```

[ASP.NET MapAction](#) with natural types for method groups:

```
[HttpGet("/")] Todo GetTodo() => new(Id: 0, Name: "Name");
app.MapAction(GetTodo);

[HttpPost("/")] Todo PostTodo([FromBody] Todo todo) => todo;
app.MapAction(PostTodo);
```

[ASP.NET MapAction](#) with attributes and natural types for lambda expressions:

```
app.MapAction([HttpGet("/")] () => new Todo(Id: 0, Name: "Name"));
app.MapAction([HttpPost("/")] ([FromBody] Todo todo) => todo);
```

Attributes

Attributes may be added to lambda expressions and lambda parameters. To avoid ambiguity between method attributes and parameter attributes, a lambda expression with attributes must use a parenthesized parameter list. Parameter types are not required.

```
f = [A] () => { };           // [A] lambda
f = [return:A] x => x;        // syntax error at '>'
f = [return:A] (x) => x;      // [A] lambda
f = [A] static x => x;        // syntax error at '>'

f = ([A] x) => x;             // [A] x
f = ([A] ref int x) => x;     // [A] x
```

Multiple attributes may be specified, either comma-separated within the same attribute list or as separate attribute lists.

```
var f = [A1, A2][A3] () => { };    // ok
var g = ([A1][A2, A3] int x) => x; // ok
```

Attributes are not supported for *anonymous methods* declared with `delegate { }` syntax.

```
f = [A] delegate { return 1; };      // syntax error at 'delegate'
f = delegate ([A] int x) { return x; }; // syntax error at '['
```

The parser will look ahead to differentiate a collection initializer with an element assignment from a collection initializer with a lambda expression.

```
var y = new C { [A] = x };    // ok: y[A] = x
var z = new C { [A] x => x }; // ok: z[0] = [A] x => x
```

The parser will treat `?[` as the start of a conditional element access.

```
x = b ? [A];                // ok
y = b ? [A] () => { } : z;    // syntax error at '('
```

Attributes on the lambda expression or lambda parameters will be emitted to metadata on the method that maps to the lambda.

In general, customers should not depend on how lambda expressions and local functions map from source to metadata. How lambdas and local functions are emitted can, and has, changed between compiler versions.

The changes proposed here are targeted at the `Delegate` driven scenario. It should be valid to inspect the `MethodInfo` associated with a `Delegate` instance to determine the signature of the lambda expression or local function including any explicit attributes and additional metadata emitted by the compiler such as default parameters. This allows teams such as ASP.NET to make available the same behaviors for lambdas and local functions as ordinary methods.

Explicit return type

An explicit return type may be specified before the parenthesized parameter list.

```
f = T () => default;          // ok
f = short x => 1;              // syntax error at '>'
f = ref int (ref int x) => ref x; // ok
f = static void (_) => { };      // ok
f = async async (async async) => async; // ok?
```

The parser will look ahead to differentiate a method call `T()` from a lambda expression `T () => e`.

Explicit return types are not supported for anonymous methods declared with `delegate { }` syntax.

```
f = delegate int { return 1; };           // syntax error
f = delegate int (int x) { return x; };   // syntax error
```

Method type inference should make an exact inference from an explicit lambda return type.

```
static void F<T>(Func<T, T> f) { ... }
F(int (i) => i); // Func<int, int>
```

Variance conversions are not allowed from lambda return type to delegate return type (matching similar behavior for parameter types).

```
Func<object> f1 = string () => null; // error
Func<object?> f2 = object () => x;   // warning
```

The parser allows lambda expressions with `ref` return types within expressions without additional parentheses.

```
d = ref int () => x; // d = (ref int () => x)
F(ref int () => x); // F((ref int () => x))
```

`var` cannot be used as an explicit return type for lambda expressions.

```
class var { }

d = var (var v) => v;           // error: contextual keyword 'var' cannot be used as explicit lambda
return type
d = @var (var v) => v;          // ok
d = ref var (ref var v) => ref v; // error: contextual keyword 'var' cannot be used as explicit lambda
return type
d = ref @var (ref var v) => ref v; // ok
```

Natural (function) type

An *anonymous function expression* (a *lambda expression* or an *anonymous method*) has a natural type if the parameters types are explicit and the return type is either explicit or can be inferred (see [inferred return type](#)).

A *method group* has a natural type if all candidate methods in the method group have a common signature. (If the method group may include extension methods, the candidates include the containing type and all extension method scopes.)

The natural type of an anonymous function expression or method group is a *function_type*. A *function_type* represents a method signature: the parameter types and ref kinds, and return type and ref kind. Anonymous function expressions or method groups with the same signature have the same *function_type*.

Function_types are used in a few specific contexts only:

- implicit and explicit conversions
- [method type inference](#) and [best common type](#)
- `var` initializers

A *function_type* exists at compile time only: *function_types* do not appear in source or metadata.

Conversions

From a *function_type* `F` there are implicit *function_type* conversions:

- To a *function_type* `G` if the parameters and return types of `F` are variance-convertible to the parameters and return type of `G`
- To `System.MulticastDelegate` or base classes or interfaces of `System.MulticastDelegate`
- To `System.Linq.Expressions.Expression` or `System.Linq.Expressions.LambdaExpression`

Anonymous function expressions and method groups already have *conversions from expression* to delegate types and expression tree types (see [anonymous function conversions](#) and [method group conversions](#)). Those conversions are sufficient for converting to strongly-typed delegate types and expression tree types. The *function_type* conversions above add *conversions from type* to the base types only: `System.MulticastDelegate`, `System.Linq.Expressions.Expression`, etc.

There are no conversions to a *function_type* from a type other than a *function_type*. There are no explicit conversions for *function_types* since *function_types* cannot be referenced in source.

A conversion to `System.MulticastDelegate` or base type or interface realizes the anonymous function or method group as an instance of an appropriate delegate type. A conversion to `System.Linq.Expressions.Expression<TDelegate>` or base type realizes the lambda expression as an expression tree with an appropriate delegate type.

```
Delegate d = delegate (object obj) { }; // Action<object>
Expression e = () => "";                // Expression<Func<string>>
object o = "".Clone;                   // Func<object>
```

Function_type conversions are not implicit or explicit [standard conversions](#) and are not considered when determining whether a user-defined conversion operator is applicable to an anonymous function or method group. From [evaluation of user defined conversions](#):

For a conversion operator to be applicable, it must be possible to perform a standard conversion ([Standard conversions](#)) from the source type to the operand type of the operator, and it must be possible to perform a standard conversion from the result type of the operator to the target type.

```
class C
{
    public static implicit operator C(Delegate d) { ... }
}

C c;
c = () => 1;      // error: cannot convert lambda expression to type 'C'
c = (C) (() => 2); // error: cannot convert lambda expression to type 'C'
```

A warning is reported for an implicit conversion of a method group to `object`, since the conversion is valid but perhaps unintentional.

```
Random r = new Random();
object obj;
obj = r.NextDouble;           // warning: Converting method group to 'object'. Did you intend to invoke the method?
obj = (object)r.NextDouble; // ok
```

Type inference

The existing rules for type inference are mostly unchanged (see [type inference](#)). There are however a **couple of changes** below to specific phases of type inference.

First phase

The [first phase](#) allows an anonymous function to bind to T_i even if T_i is not a delegate or expression tree type (perhaps a type parameter constrained to `System.Delegate` for instance).

For each of the method arguments E_i :

- If E_i is an anonymous function and T_i is a delegate type or expression tree type, an *explicit parameter type inference* is made from E_i to T_i and an *explicit return type inference* is made from E_i to T_i .
- Otherwise, if E_i has a type U and x_i is a value parameter then a *lower-bound inference* is made from U to T_i .
- Otherwise, if E_i has a type U and x_i is a `ref` or `out` parameter then an *exact inference* is made from U to T_i .
- Otherwise, no inference is made for this argument.

Explicit return type inference

An *explicit return type inference* is made from an expression E to a type T in the following way:

- If E is an anonymous function with explicit return type U_r and T is a delegate type or expression tree type with return type V_r then an *exact inference* ([Exact inferences](#)) is made from U_r to V_r .

Fixing

[Fixing](#) ensures other conversions are preferred over *function_type* conversions. (Lambda expressions and method group expressions only contribute to lower bounds so handling of *function_types* is needed for lower bounds only.)

An *unfixed* type variable x_i with a set of bounds is *fixed* as follows:

- The set of *candidate types* u_j starts out as the set of all types in the set of bounds for x_i where **function types are ignored in lower bounds if there any types that are not function types**.
- We then examine each bound for x_i in turn: For each exact bound u of x_i all types u_j which are not identical to u are removed from the candidate set. For each lower bound u of x_i all types u_j to which there is *not* an implicit conversion from u are removed from the candidate set. For each upper bound u of x_i all types u_j from which there is *not* an implicit conversion to u are removed from the candidate set.
- If among the remaining candidate types u_j there is a unique type v from which there is an implicit conversion to all the other candidate types, then x_i is fixed to v .
- Otherwise, type inference fails.

Best common type

[Best common type](#) is defined in terms of type inference so the type inference changes above apply to best common type as well.

```
var fs = new[] { (string s) => s.Length; (string s) => int.Parse(s) } // Func<string, int>[]
```

`var`

Anonymous functions and method groups with function types can be used as initializers in `var` declarations.

```

var f1 = () => default;           // error: cannot infer type
var f2 = x => x;                  // error: cannot infer type
var f3 = () => 1;                 // System.Func<int>
var f4 = string () => null;       // System.Func<string>
var f5 = delegate (object o) { }; // System.Action<object>

static void F1() { }
static void F1<T>(this T t) { }
static void F2(this string s) { }

var f6 = F1;    // error: multiple methods
var f7 = "", F1; // System.Action
var f8 = F2;    // System.Action<string>

```

Function types are not used in assignments to discards.

```

d = () => 0; // ok
_ = () => 1; // error

```

Delegate types

The delegate type for the anonymous function or method group with parameter types `P1, ..., Pn` and return type `R` is:

- if any parameter or return value is not by value, or there are more than 16 parameters, or any of the parameter types or return are not valid type arguments (say, `(int* p) => { }`), then the delegate is a synthesized `internal` anonymous delegate type with signature that matches the anonymous function or method group, and with parameter names `arg1, ..., argn` or `arg` if a single parameter;
- if `R` is `void`, then the delegate type is `System.Action<P1, ..., Pn>`;
- otherwise the delegate type is `System.Func<P1, ..., Pn, R>`.

The compiler may allow more signatures to bind to `System.Action<>` and `System.Func<>` types in the future (if `ref struct` types are allowed type arguments for instance).

`modopt()` or `modreq()` in the method group signature are ignored in the corresponding delegate type.

If two anonymous functions or method groups in the same compilation require synthesized delegate types with the same parameter types and modifiers and the same return type and modifiers, the compiler will use the same synthesized delegate type.

Overload resolution

[Better function member](#) is updated to prefer members where none of the conversions and none of the type arguments involved inferred types from lambda expressions or method groups.

Better function member

... Given an argument list `A` with a set of argument expressions `{E1, E2, ..., En}` and two applicable function members `Mp` and `Mq` with parameter types `{P1, P2, ..., Pn}` and `{Q1, Q2, ..., Qn}`, `Mp` is defined to be a **better function member** than `Mq` if

1. for each argument, the implicit conversion from `Ex` to `Px` is not a *function_type_conversion*, and
 - `Mp` is a non-generic method or `Mp` is a generic method with type parameters `{X1, X2, ..., Xp}` and for each type parameter `Xi` the type argument is inferred from an expression or from a type other than a *function_type*, and
 - for at least one argument, the implicit conversion from `Ex` to `Qx` is a *function_type_conversion*, or `Mq` is a generic method with type parameters

`{Y1, Y2, ..., Yq}` and for at least one type parameter `Yi` the type argument is inferred from a *function_type*, or

- for each argument, the implicit conversion from `Ex` to `Qx` is not better than the implicit conversion from `Ex` to `Px`, and for at least one argument, the conversion from `Ex` to `Px` is better than the conversion from `Ex` to `Qx`.

[Better conversion from expression](#) is updated to prefer conversions that did not involve inferred types from lambda expressions or method groups.

Better conversion from expression

Given an implicit conversion `c1` that converts from an expression `E` to a type `T1`, and an implicit conversion `c2` that converts from an expression `E` to a type `T2`, `c1` is a *better conversion* than `c2` if:

- `c1` is not a *function_type_conversion* and `c2` is a *function_type_conversion*, or
- `E` is a non-constant *interpolated_string_expression*, `c1` is an *implicit_string_handler_conversion*, `T1` is an *applicable_interpolated_string_handler_type*, and `c2` is not an *implicit_string_handler_conversion*, or
- `E` does not exactly match `T2` and at least one of the following holds:
 - `E` exactly matches `T1` ([Exactly matching Expression](#))
 - `T1` is a better conversion target than `T2` ([Better conversion target](#))

Syntax

```
lambda_expression
: modifier* identifier '=>' (block | expression)
| attribute_list* modifier* type? lambda_parameters '=>' (block | expression)
;

lambda_parameters
: lambda_parameter
| '(' (lambda_parameter (',' lambda_parameter)*)? ')'
;

lambda_parameter
: identifier
| attribute_list* modifier* type? identifier equals_value_clause?
;
```

Open issues

Should default values be supported for lambda expression parameters for completeness?

Should `System.Diagnostics.ConditionalAttribute` be disallowed on lambda expressions since there are few scenarios where a lambda expression could be used conditionally?

```
([Conditional("DEBUG")] static (x, y) => Assert(x == y))(a, b); // ok?
```

Should the *function_type* be available from the compiler API, in addition to the resulting delegate type?

Currently, the inferred delegate type uses `System.Action<>` or `System.Func<>` when parameter and return types are valid type arguments *and* there are no more than 16 parameters, and if the expected `Action<>` or `Func<>` type is missing, an error is reported. Instead, should the compiler use `System.Action<>` or `System.Func<>` regardless of arity? And if the expected type is missing, synthesize a delegate type otherwise?

CallerArgumentExpression

12/28/2021 • 7 minutes to read • [Edit Online](#)

Summary

Allow developers to capture the expressions passed to a method, to enable better error messages in diagnostic/testing APIs and reduce keystrokes.

Motivation

When an assertion or argument validation fails, the developer wants to know as much as possible about where and why it failed. However, today's diagnostic APIs do not fully facilitate this. Consider the following method:

```
T Single<T>(this T[] array)
{
    Debug.Assert(array != null);
    Debug.Assert(array.Length == 1);

    return array[0];
}
```

When one of the asserts fail, only the filename, line number, and method name will be provided in the stack trace. The developer will not be able to tell which assert failed from this information-- (s)he will have to open the file and navigate to the provided line number to see what went wrong.

This is also the reason testing frameworks have to provide a variety of assert methods. With xUnit, `Assert.True` and `Assert.False` are not frequently used because they do not provide enough context about what failed.

While the situation is a bit better for argument validation because the names of invalid arguments are shown to the developer, the developer must pass these names to exceptions manually. If the above example were rewritten to use traditional argument validation instead of `Debug.Assert`, it would look like

```
T Single<T>(this T[] array)
{
    if (array == null)
    {
        throw new ArgumentNullException(nameof(array));
    }

    if (array.Length != 1)
    {
        throw new ArgumentException("Array must contain a single element.", nameof(array));
    }

    return array[0];
}
```

Notice that `nameof(array)` must be passed to each exception, although it's already clear from context which argument is invalid.

Detailed design

In the above examples, including the string `"array != null"` or `"array.Length == 1"` in the assert message

would help the developer determine what failed. Enter `CallerArgumentExpression`: it's an attribute the framework can use to obtain the string associated with a particular method argument. We would add it to `Debug.Assert` like so

```
public static class Debug
{
    public static void Assert(bool condition, [CallerArgumentExpression("condition")] string message = null);
}
```

The source code in the above example would stay the same. However, the code the compiler actually emits would correspond to

```
T Single<T>(this T[] array)
{
    Debug.Assert(array != null, "array != null");
    Debug.Assert(array.Length == 1, "array.Length == 1");

    return array[0];
}
```

The compiler specially recognizes the attribute on `Debug.Assert`. It passes the string associated with the argument referred to in the attribute's constructor (in this case, `condition`) at the call site. When either assert fails, the developer will be shown the condition that was false and will know which one failed.

For argument validation, the attribute cannot be used directly, but can be made use of through a helper class:

```

public static class Verify
{
    public static void Argument(bool condition, string message, [CallerArgumentExpression("condition")]
string conditionExpression = null)
    {
        if (!condition) throw new ArgumentException(message: message, paramName: conditionExpression);
    }

    public static void InRange(int argument, int low, int high,
        [CallerArgumentExpression("argument")] string argumentExpression = null,
        [CallerArgumentExpression("low")] string lowExpression = null,
        [CallerArgumentExpression("high")] string highExpression = null)
    {
        if (argument < low)
        {
            throw new ArgumentOutOfRangeException(paramName: argumentExpression,
                message: $"{argumentExpression} ({argument}) cannot be less than {lowExpression} ({low}).");
        }

        if (argument > high)
        {
            throw new ArgumentOutOfRangeException(paramName: argumentExpression,
                message: $"{argumentExpression} ({argument}) cannot be greater than {highExpression}
({high}).");
        }
    }

    public static void NotNull<T>(T argument, [CallerArgumentExpression("argument")] string
argumentExpression = null)
        where T : class
    {
        if (argument == null) throw new ArgumentNullException(paramName: argumentExpression);
    }
}

T Single<T>(this T[] array)
{
    Verify.NotNull(array); // paramName: "array"
    Verify.Argument(array.Length == 1, "Array must contain a single element."); // paramName: "array.Length
== 1"

    return array[0];
}

T ElementAt(this T[] array, int index)
{
    Verify.NotNull(array); // paramName: "array"
    // paramName: "index"
    // message: "index (-1) cannot be less than 0 (0).", or
    // "index (6) cannot be greater than array.Length - 1 (5)."
    Verify.InRange(index, 0, array.Length - 1);

    return array[index];
}

```

A proposal to add such a helper class to the framework is underway at <https://github.com/dotnet/corefx/issues/17068>. If this language feature was implemented, the proposal could be updated to take advantage of this feature.

Extension methods

The `this` parameter in an extension method may be referenced by `CallerArgumentExpression`. For example:

```
public static void ShouldBe<T>(this T @this, T expected, [CallerArgumentExpression("this")] string
thisExpression = null) {}
```

```
contestant.Points.ShouldBe(1337); // thisExpression: "contestant.Points"
```

`thisExpression` will receive the expression corresponding to the object before the dot. If it's called with static method syntax, e.g. `Ext.ShouldBe(contestant.Points, 1337)`, it will behave as if first parameter wasn't marked `this`.

There should always be an expression corresponding to the `this` parameter. Even if an instance of a class calls an extension method on itself, e.g. `this.Single()` from inside a collection type, the `this` is mandated by the compiler so `"this"` will get passed. If this rule is changed in the future, we can consider passing `null` or the empty string.

Extra details

- Like the other `Caller*` attributes, such as `CallerMemberName`, this attribute may only be used on parameters with default values.
- Multiple parameters marked with `CallerArgumentExpression` are permitted, as shown above.
- The attribute's namespace will be `System.Runtime.CompilerServices`.
- If `null` or a string that is not a parameter name (e.g. `"notAParameterName"`) is provided, the compiler will pass in an empty string.
- The type of the parameter `CallerArgumentExpressionAttribute` is applied to must have a standard conversion from `string`. This means no user-defined conversions from `string` are allowed, and in practice means the type of such a parameter must be `string`, `object`, or an interface implemented by `string`.

Drawbacks

- People who know how to use decompilers will be able to see some of the source code at call sites for methods marked with this attribute. This may be undesirable/unexpected for closed-source software.
- Although this is not a flaw in the feature itself, a source of concern may be that there exists a `Debug.Assert` API today that only takes a `bool`. Even if the overload taking a message had its second parameter marked with this attribute and made optional, the compiler would still pick the no-message one in overload resolution. Therefore, the no-message overload would have to be removed to take advantage of this feature, which would be a binary (although not source) breaking change.

Alternatives

- If being able to see source code at call sites for methods that use this attribute proves to be a problem, we can make the attribute's effects opt-in. Developers will enable it through an assembly-wide `[assembly: EnableCallerArgumentExpression]` attribute they put in `AssemblyInfo.cs`.
 - In the case the attribute's effects are not enabled, calling methods marked with the attribute would not be an error, to allow existing methods to use the attribute and maintain source compatibility. However, the attribute would be ignored and the method would be called with whatever default value was provided.

```

// Assembly1

void Foo(string bar); // V1
void Foo(string bar, string barExpression = "not provided"); // V2
void Foo(string bar, [CallerArgumentExpression("bar")] string barExpression = "not provided"); // V3

// Assembly2

Foo(a); // V1: Compiles to Foo(a), V2, V3: Compiles to Foo(a, "not provided")
Foo(a, "provided"); // V2, V3: Compiles to Foo(a, "provided")

// Assembly3

[assembly: EnableCallerArgumentExpression]

Foo(a); // V1: Compiles to Foo(a), V2: Compiles to Foo(a, "not provided"), V3: Compiles to Foo(a, "a")
Foo(a, "provided"); // V2, V3: Compiles to Foo(a, "provided")

```

- To prevent the [binary compatibility problem](#) from occurring every time we want to add new caller info to `Debug.Assert`, an alternative solution would be to add a `CallerInfo` struct to the framework that contains all the necessary information about the caller.

```

struct CallerInfo
{
    public string MemberName { get; set; }
    public string TypeName { get; set; }
    public string Namespace { get; set; }
    public string FullTypeName { get; set; }
    public string FilePath { get; set; }
    public int LineNumber { get; set; }
    public int ColumnNumber { get; set; }
    public Type Type { get; set; }
    public MethodBase Method { get; set; }
    public string[] ArgumentExpressions { get; set; }
}

[Flags]
enum CallerInfoOptions
{
    MemberName = 1, TypeName = 2, ...
}

public static class Debug
{
    public static void Assert(bool condition,
        // If a flag is not set here, the corresponding CallerInfo member is not populated by the caller, so
        // it's pay-for-play friendly.
        [CallerInfo(CallerInfoOptions.FilePath | CallerInfoOptions.Method |
        CallerInfoOptions.ArgumentExpressions)] CallerInfo callerInfo = default(CallerInfo))
    {
        string filePath = callerInfo.FilePath;
        MethodBase method = callerInfo.Method;
        string conditionExpression = callerInfo.ArgumentExpressions[0];
        ...
    }
}

class Bar
{
    void Foo()
    {
        Debug.Assert(false);

        // Translates to:

        var callerInfo = new CallerInfo();
        callerInfo.FilePath = @"C:\Bar.cs";
        callerInfo.Method = MethodBase.GetCurrentMethod();
        callerInfo.ArgumentExpressions = new string[] { "false" };
        Debug.Assert(false, callerInfo);
    }
}

```

This was originally proposed at <https://github.com/dotnet/csharp-lang/issues/87>.

There are a few disadvantages of this approach:

- Despite being pay-for-play friendly by allowing you to specify which properties you need, it could still hurt perf significantly by allocating an array for the expressions/calling `MethodBase.GetCurrentMethod` even when the assert passes.
- Additionally, while passing a new flag to the `CallerInfo` attribute won't be a breaking change, `Debug.Assert` won't be guaranteed to actually receive that new parameter from call sites that compiled against an old version of the method.

Enhanced #line directives

12/28/2021 • 8 minutes to read • [Edit Online](#)

Summary

The compiler applies the mapping defined by `#line` directives to diagnostic locations and sequence points emitted to the PDB.

Currently only the line number and file path can be mapped while the starting character is inferred from the source code. The proposal is to allow specifying full span mapping.

Motivation

DSLs that generate C# source code (such as ASPNET Razor) can't currently produce precise source mapping using `#line` directives. This results in degraded debugging experience in some cases as the sequence points emitted to the PDB can't map to the precise location in the original source code.

For example, the following Razor code

```
@page "/"
Time: @DateTime.Now
```

generates code like so (simplified):

```
#line hidden
void Render()
{
    _builder.Add("Time:");
    #line 2 "page.razor"
    _builder.Add(DateTime.Now);
    #line hidden
}
```

The above directive would map the sequence point emitted by the compiler for the `_builder.Add(DateTime.Now);` statement to the line 2, but the column would be off (16 instead of 7).

The Razor source generator actually incorrectly generates the following code:

```
#line hidden
void Render()
{
    _builder.Add("Time:");
    _builder.Add(
    #line 2 "page.razor"
        DateTime.Now
    #line hidden
    );
}
```

The intent was to preserve the starting character and it works for diagnostic location mapping. However, this does not work for sequence points since `#line` directive only applies to the sequence points that follow it. There is no sequence point in the middle of the `_builder.Add(DateTime.Now);` statement (sequence points can only be emitted at IL instructions with empty evaluation stack). The `#line 2` directive in above code thus has no

effect on the generated PDB and the debugger won't place a breakpoint or stop on the `@DateTime.Now` snippet in the Razor page.

Issues addressed by this proposal: <https://github.com/dotnet/roslyn/issues/43432>
<https://github.com/dotnet/roslyn/issues/46526>

Detailed design

We amend the syntax of `line_indicator` used in `pp_line` directive like so:

Current:

```
line_indicator
: decimal_digit+ whitespace file_name
| decimal_digit+
| 'default'
| 'hidden'
;
```

Proposed:

```
line_indicator
: '(' decimal_digit+ ',' decimal_digit+ ')' '-' '(' decimal_digit+ ',' decimal_digit+ ')' decimal_digit+
whitespace file_name
| '(' decimal_digit+ ',' decimal_digit+ ')' '-' '(' decimal_digit+ ',' decimal_digit+ ')' file_name
| decimal_digit+ whitespace file_name
| decimal_digit+
| 'default'
| 'hidden'
;
```

That is, the `#line` directive would accept either 5 decimal numbers (*start line, start character, end line, end character, character offset*), 4 decimal numbers (*start line, start character, end line, end character*), or a single one (*line*).

If *character offset* is not specified its default value is 0, otherwise it specifies the number of UTF-16 characters. The number must be non-negative and less than length of the line following the `#line` directive in the unmapped file.

(*start line, start character*)-(*end line, end character*) specifies a span in the mapped file. *start line* and *end line* are positive integers that specify line numbers. *start character, end character* are positive integers that specify UTF-16 character numbers. *start line, start character, end line, end character* are 1-based, meaning that the first line of the file and the first UTF-16 character on each line is assigned number 1.

The implementation would constraint these numbers so that they specify a valid [sequence point source span](#):

- *start line* - 1 is within range [0, 0x20000000) and not equal to 0xfeefee.
- *end line* - 1 is within range [0, 0x20000000) and not equal to 0xfeefee.
- *start character* - 1 is within range [0, 0x10000)
- *end character* - 1 is within range [0, 0x10000)
- *end line* is greater or equal to *start line*.
- *start line* is equal to *end line* then *end character* is greater than *start character*.

Note that the numbers specified in the directive syntax are 1-based numbers but the actual spans in the PDB are zero-based. Hence the -1 adjustments above.

The mapped spans of sequence points and the locations of diagnostics that `#line` directive applies to are calculated as follows.

Let d be the zero-based number of the unmapped line containing the `#line` directive. Let span $L = (\text{start: } (\text{start line} - 1, \text{start character} - 1), \text{end: } (\text{end line} - 1, \text{end character} - 1))$ be zero-based span specified by the directive.

Function M that maps a position (line, character) within the scope of the `#line` directive in the source file containing the `#line` directive to a mapped position (mapped line, mapped character) is defined as follows:

$M(l, c) =$

$l = d + 1 \Rightarrow (L.\text{start.line} + l - d - 1, L.\text{start.character} + \max(c - \text{character offset}, 0))$ $l > d + 1 \Rightarrow (L.\text{start.line} + l - d - 1, c)$

The syntax constructs that sequence points are associated with are determined by the compiler implementation and not covered by this specification. The compiler also decides for each sequence point its unmapped span. This span may partially or fully cover the associated syntax construct.

Once the unmapped spans are determined by the compiler the function M defined above is applied to their starting and ending positions, with the exception of the ending position of all sequence points within the scope of the `#line` directive whose unmapped location is at line $d + 1$ and character less than character offset. The end position of all these sequence points is $L.\text{end}$.

Example [5.i] demonstrates why it is necessary to provide the ability to specify the end position of the first sequence point span.

The above definition allows the generator of the unmapped source code to avoid intimate knowledge of which exact source constructs of the C# language produce sequence points. The mapped spans of the sequence points in the scope of the `#line` directive are derived from the relative position of the corresponding unmapped spans to the first unmapped span.

Specifying the *character offset* allows the generator to insert any single-line prefix on the first line. This prefix is generated code that is not present in the mapped file. Such inserted prefix affects the value of the first unmapped sequence point span. Therefore the starting character of subsequent sequence point spans need to be offset by the length of the prefix (*character offset*). See example [2].

Examples

For clarity the examples use `spanof('...')` and `lineof('...')` pseudo-syntax to express the mapped span start position and line number, respectively, of the specified code snippet.

1. First and subsequent spans

Consider the following code with unmapped zero-based line numbers listed on the right:

```
#line 1 10 1 15 "a"    // 3
  A();B(              // 4
);C();                // 5
  D();                // 6
```

$d = 3 \quad L = (0, 9)..(0, 14)$

There are 4 sequence point spans the directive applies to with following unmapped and mapped spans: $(4, 2)..(4, 5) \Rightarrow (0, 9)..(0, 14)$ $(4, 6)..(5, 1) \Rightarrow (0, 15)..(1, 1)$ $(5, 2)..(5, 5) \Rightarrow (1, 2)..(1, 5)$ $(6, 4)..(6, 7) \Rightarrow (2, 4)..(2, 7)$

2. Character offset

Razor generates `_builder.Add(` prefix of length 15 (including two leading spaces).

Razor:

```
@page "/"
@F( ) => 1+1,
    ( ) => 2+2
)
```

Generated C#:

```
#line hidden
void Render()
{
#line spanof('F(...)') 15 "page.razor" // 4
  _builder.Add(F( ) => 1+1,           // 5
    ( ) => 2+2                        // 6
  ));                                // 7
#line hidden
}
);
}
```

$d = 4 \quad L = (1, 1)..(3, 0)$ *character offset* = 15

Spans:

- `_builder.Add(F(...));` \Rightarrow `F(...)` : $(5, 2)..(7, 2) \Rightarrow (1, 1)..(3, 0)$
- `1+1` \Rightarrow `1+1` : $(5, 23)..(5, 25) \Rightarrow (1, 9)..(1, 11)$
- `2+2` \Rightarrow `2+2` : $(6, 7)..(6, 9) \Rightarrow (2, 7)..(2, 9)$

3. Razor: Single-line span

Razor:

```
@page "/"
Time: @DateTime.Now
```

Generated C#:

```
#line hidden
void Render()
{
    _builder.Add("Time:");
#line spanof('DateTime.Now') 15 "page.razor"
    _builder.Add(DateTime.Now);
#line hidden
};
}
```

4. Razor: Multi-line span

Razor:

```
@page "/"
@JsonToHtml(@"
{
    ""key1"": "value1",
    ""key2"": "value2"
}")
```

Generated C#:

```
#line hidden
void Render()
{
    _builder.Add("Time:");
#line spanof('JsonToHtml(@"..."') 15 "page.razor"
    _builder.Add(JsonToHtml(@"
{
    ""key1"": "value1",
    ""key2"": "value2"
}"));
#line hidden
}
};
}
```

5. Razor: block constructs

i. block containing expressions

In this example, the mapped span of the first sequence point that is associated with the IL instruction that is emitted for the `_builder.Add(Html.Helper(() =>` statement needs to cover the whole expression of `Html.Helper(...)` in the generated file `a.razor`. This is achieved by application of rule [1] to the end position of the sequence point.

```
@Html.Helper(() =>
{
    <p>Hello World</p>
    @DateTime.Now
})
```

```
#line spanof('Html.Helper(() => { ... }')) 13 "a.razor"
_builder.Add(Html.Helper(() =>
#line lineof('{}') "a.razor"
{
#line spanof('DateTime.Now') 13 "a.razor"
_builder.Add(DateTime.Now);
#line lineof('{}') "a.razor"
}
#line hidden
)
```

ii. block containing statements

Uses existing `#line line file` form since

a) Razor does not add any prefix, b) `{` is not present in the generated file and there can't be a sequence point placed on it, therefore the span of the first unmapped sequence point is unknown to Razor.

The starting character of `Console` in the generated file must be aligned with the Razor file.

```
@{Console.WriteLine(1);Console.WriteLine(2);}
```

```
#line lineof('@{}') "a.razor"
    Console.WriteLine(1);Console.WriteLine(2);
#line hidden
```

iii. block containing top-level code (@code, @functions)

Uses existing `#line line file` form since

a) Razor does not add any prefix, b) `{` is not present in the generated file and there can't be a sequence point placed on it, therefore the span of the first unmapped sequence point is unknown to Razor.

The starting character of `[Parameter]` in the generated file must be aligned with the Razor file.

```
@code {
    [Parameter]
    public int IncrementAmount { get; set; }
}
```

```
#line lineof('[{}') "a.razor"
    [Parameter]
    public int IncrementAmount { get; set; }
#line hidden
```

6. Razor: `@for`, `@foreach`, `@while`, `@do`, `@if`, `@switch`, `@using`, `@try`, `@lock`

Uses existing `#line line file` form since a) Razor does not add any prefix. b) the span of the first unmapped sequence point may not be known to Razor (or shouldn't need to know).

The starting character of the keyword in the generated file must be aligned with the Razor file.

```
@for (var i = 0; i < 10; i++)  
{  
}  
@if (condition)  
{  
}  
else  
{  
}
```

```
#line lineof('for') "a.razor"  
for (var i = 0; i < 10; i++)  
{  
}  
#line lineof('if') "a.razor"  
if (condition)  
{  
}  
else  
{  
}  
#line hidden
```

Generic Attributes

12/28/2021 • 2 minutes to read • [Edit Online](#)

Summary

When generics were introduced in C# 2.0, attribute classes were not allowed to participate. We can make the language more composable by removing (rather, loosening) this restriction. The .NET Core runtime has added support for generic attributes. Now, all that's missing is support for generic attributes in the compiler.

Motivation

Currently attribute authors can take a `System.Type` as a parameter and have users pass a `typeof` expression to provide the attribute with types that it needs. However, outside of analyzers, there's no way for an attribute author to constrain what types are allowed to be passed to an attribute via `typeof`. If attributes could be generic, then attribute authors could use the existing system of type parameter constraints to express the requirements for the types they take as input.

Detailed design

The following section is amended: <https://github.com/dotnet/csharplang/blob/main/spec/classes.md#base-classes>

The direct base class of a class type must not be any of the following types: `System.Array`, `System.Delegate`, `System.MulticastDelegate`, `System.Enum`, or `System.ValueType`. Furthermore, a generic class declaration cannot use `System.Attribute` as a direct or indirect base class.

One important note is that the following section of the spec is *unaffected* when referencing the point of usage of an attribute, i.e. within an attribute list: <https://github.com/dotnet/csharplang/blob/main/spec/types.md#type-parameters>

A type parameter cannot be used anywhere within an attribute.

This means that when a generic attribute is used, its construction needs to be fully "closed", i.e. not containing any type parameters, which means the following is still disallowed:

```
using System;
using System.Collections.Generic;

public class Attr<T1> : Attribute { }

public class Program<T2>
{
    [Attr<T2>] // error
    [Attr<List<T2>>] // error
    void M() { }
}
```

When a generic attribute is used in an attribute list, its type arguments have the same restrictions that `typeof` has on its argument. For example, `[Attr<dynamic>]` is an error. This is because "attribute-dependent" types like `dynamic`, `List<string?>`, `nint`, and so on can't be fully represented in the final IL for an attribute type argument, because there isn't a symbol to "attach" the `DynamicAttribute` or other well-known attribute to.

Drawbacks

Removing the restriction, reasoning out the implications, and adding the appropriate tests is work.

Alternatives

Attribute authors who want users to be able to discover the requirements for the types they provide to attributes need to write analyzers and guide their users to use those analyzers in their builds.

Unresolved questions

- [x] What does `AllowMultiple = false` mean on a generic attribute? If we have `[Attr<string>]` and `[Attr<object>]` both used on a symbol, does that mean "multiple" of the attribute are in use?
 - For now we are inclined to take the more restrictive route here and consider the attribute class's original definition when deciding whether multiple of it have been applied. In other words, `[Attr<string>]` and `[Attr<object>]` applied together is incompatible with `AllowMultiple = false`.

Design meetings

- <https://github.com/dotnet/csharplang/blob/main/meetings/2017/LDM-2017-02-21.md#generic-attributes>
 - At the time there was a concern that we would have to gate the feature on whether the target runtime supports it. (However, we now only support C# 10 on .NET 6. It would be nice to for the implementation to be aware of what minimum target framework supports the feature, but seems less essential today.)

Improved Definite Assignment Analysis

12/28/2021 • 13 minutes to read • [Edit Online](#)

Summary

[Definite assignment analysis](#) as specified has a few gaps which have caused users inconvenience. In particular, scenarios involving comparison to boolean constants, conditional-access, and null coalescing.

Related discussions and issues

csharp-lang discussion of this proposal: <https://github.com/dotnet/csharp-lang/discussions/4240>

Probably a dozen or so user reports can be found via this or similar queries (i.e. search for "definite assignment" instead of "CS0165", or search in csharp-lang). <https://github.com/dotnet/roslyn/issues?q=is%3Aclosed+is%3Aissue+label%3A%22Resolution-By+Design%22+cs0165>

I have included related issues in the scenarios below to give a sense of the relative impact of each scenario.

Scenarios

As a point of reference, let's start with a well-known "happy case" that does work in definite assignment and in nullable.

```
#nullable enable

C c = new C();
if (c != null && c.M(out object obj0))
{
    obj0.ToString(); // ok
}

public class C
{
    public bool M(out object obj)
    {
        obj = new object();
        return true;
    }
}
```

Comparison to bool constant

- <https://github.com/dotnet/csharp-lang/discussions/801>
- <https://github.com/dotnet/roslyn/issues/45582>
 - Links to 4 other issues where people were affected by this.

```

if ((c != null && c.M(out object obj1)) == true)
{
    obj1.ToString(); // undesired error
}

if ((c != null && c.M(out object obj2)) is true)
{
    obj2.ToString(); // undesired error
}

```

Comparison between a conditional access and a constant value

- <https://github.com/dotnet/roslyn/issues/33559>
- <https://github.com/dotnet/csharp-lang/discussions/4214>
- <https://github.com/dotnet/csharp-lang/issues/3659>
- <https://github.com/dotnet/csharp-lang/issues/3485>
- <https://github.com/dotnet/csharp-lang/issues/3659>

This scenario is probably the biggest one. We do support this in nullable but not in definite assignment.

```

if (c?.M(out object obj3) == true)
{
    obj3.ToString(); // undesired error
}

```

Conditional access coalesced to a bool constant

- <https://github.com/dotnet/csharp-lang/discussions/916>
- <https://github.com/dotnet/csharp-lang/issues/3365>

This scenario is very similar to the previous one. This is also supported in nullable but not in definite assignment.

```

if (c?.M(out object obj4) ?? false)
{
    obj4.ToString(); // undesired error
}

```

Conditional expressions where one arm is a bool constant

- <https://github.com/dotnet/roslyn/issues/4272>

It's worth pointing out that we already have special behavior for when the condition expression is constant (i.e. `true ? a : b`). We just unconditionally visit the arm indicated by the constant condition and ignore the other arm.

Also note that we haven't handled this scenario in nullable.

```

if (c != null ? c.M(out object obj4) : false)
{
    obj4.ToString(); // undesired error
}

```

Specification

?. (null-conditional operator) expressions

We introduce a new section **?. (null-conditional operator) expressions**. See the [null-conditional operator specification](#) and [definite assignment rules](#) for context.

As in the definite assignment rules linked above, we refer to a given initially unassigned variable as v .

We introduce the concept of "directly contains". An expression E is said to "directly contain" a subexpression E_1 if it is not subject to a [user-defined conversion](#) whose parameter is not of a non-nullable value type, and one of the following conditions holds:

- E is E_1 . For example, `a?.b()` directly contains the expression `a?.b()`.
- If E is a parenthesized expression `(E2)`, and E_2 directly contains E_1 .
- If E is a null-forgiving operator expression `E2!`, and E_2 directly contains E_1 .
- If E is a cast expression `(T)E2`, and the cast does not subject E_2 to a non-lifted user-defined conversion whose parameter is not of a non-nullable value type, and E_2 directly contains E_1 .

For an expression E of the form `primary_expression null_conditional_operations`, let E_0 be the expression obtained by textually removing the leading `?` from each of the *null_conditional_operations* of E that have one, as in the linked specification above.

In subsequent sections we will refer to E_0 as the *non-conditional counterpart* to the null-conditional expression. Note that some expressions in subsequent sections are subject to additional rules that only apply when one of the operands directly contains a null-conditional expression.

- The definite assignment state of v at any point within E is the same as the definite assignment state at the corresponding point within E_0 .
- The definite assignment state of v after E is the same as the definite assignment state of v after *primary_expression*.

Remarks

We use the concept of "directly contains" to allow us to skip over relatively simple "wrapper" expressions when analyzing conditional accesses that are compared to other values. For example, `((a?.b(out x))!) == true` is expected to result in the same flow state as `a?.b == true` in general.

We also want to allow analysis to function in the presence of a number of possible conversions on a conditional access. Propagating out "state when not null" is not possible when the conversion is user-defined, though, since we can't count on user-defined conversions to honor the constraint that the output is non-null only if the input is non-null. The only exception to this is when the user-defined conversion's input is a non-nullable value type. For example:

```
public struct S1 { }
public struct S2 { public static implicit operator S2?(S1 s1) => null; }
```

This also includes lifted conversions like the following:

```

string x;

S1? s1 = null;
_ = s1?.M1(x = "a") ?? s1.Value.M2(x = "a");

x.ToString(); // ok

public struct S1
{
    public S1 M1(object obj) => this;
    public S2 M2(object obj) => new S2();
}
public struct S2
{
    public static implicit operator S2(S1 s1) => null;
}

```

When we consider whether a variable is assigned at a given point within a null-conditional expression, we simply assume that any preceding null-conditional operations within the same null-conditional expression succeeded.

For example, given a conditional expression `a?.b(out x)?.c(x)`, the non-conditional counterpart is `a.b(out x).c(x)`. If we want to know the definite assignment state of `x` before `?.c(x)`, for example, then we perform a "hypothetical" analysis of `a.b(out x)` and use the resulting state as an input to `?.c(x)`.

Boolean constant expressions

We introduce a new section "Boolean constant expressions":

For an expression *expr* where *expr* is a constant expression with a bool value:

- The definite assignment state of *v* after *expr* is determined by:
 - If *expr* is a constant expression with value *true*, and the state of *v* before *expr* is "not definitely assigned", then the state of *v* after *expr* is "definitely assigned when false".
 - If *expr* is a constant expression with value *false*, and the state of *v* before *expr* is "not definitely assigned", then the state of *v* after *expr* is "definitely assigned when true".

Remarks

We assume that if an expression has a constant value bool `false`, for example, it's impossible to reach any branch that requires the expression to return `true`. Therefore variables are assumed to be definitely assigned in such branches. This ends up combining nicely with the spec changes for expressions like `??` and `?:` and enabling a lot of useful scenarios.

It's also worth noting that we never expect to be in a conditional state *before* visiting a constant expression. That's why we do not account for scenarios such as "*expr* is a constant expression with value *true*, and the state of *v* before *expr* is "definitely assigned when true".

?? (null-coalescing expressions) augment

We augment the section [?? \(null coalescing\) expressions](#) as follows:

For an expression *expr* of the form `expr_first ?? expr_second`:

- ...
- The definite assignment state of *v* after *expr* is determined by:
 - ...
 - If *expr_first* directly contains a null-conditional expression *E*, and *v* is definitely assigned after the non-conditional counterpart *E₀*, then the definite assignment state of *v* after *expr* is the same as the definite assignment state of *v* after *expr_second*.

Remarks

The above rule formalizes that for an expression like `a?.M(out x) ?? (x = false)`, either the `a?.M(out x)` was fully evaluated and produced a non-null value, in which case `x` was assigned, or the `x = false` was evaluated, in which case `x` was also assigned. Therefore `x` is always assigned after this expression.

This also handles the `dict?.TryGetValue(key, out var value) ?? false` scenario, by observing that `v` is definitely assigned after `dict.TryGetValue(key, out var value)`, and `v` is "definitely assigned when true" after `false`, and concluding that `v` must be "definitely assigned when true".

The more general formulation also allows us to handle some more unusual scenarios, such as:

- `if (x?.M(out y) ?? (b && z.M(out y))) y.ToString();`
- `if (x?.M(out y) ?? z?.M(out y) ?? false) y.ToString();`

?: (conditional) expressions

We augment the section [?: \(conditional\) expressions](#) as follows:

For an expression *expr* of the form `expr_cond ? expr_true : expr_false`:

- ...
- The definite assignment state of *v* after *expr* is determined by:
 - ...
 - If the state of *v* after *expr_true* is "definitely assigned when true", and the state of *v* after *expr_false* is "definitely assigned when true", then the state of *v* after *expr* is "definitely assigned when true".
 - If the state of *v* after *expr_true* is "definitely assigned when false", and the state of *v* after *expr_false* is "definitely assigned when false", then the state of *v* after *expr* is "definitely assigned when false".

Remarks

This makes it so when both arms of a conditional expression result in a conditional state, we join the corresponding conditional states and propagate it out instead of unsplitting the state and allowing the final state to be non-conditional. This enables scenarios like the following:

```
bool b = true;
object x = null;
int y;
if (b ? x != null && Set(out y) : x != null && Set(out y))
{
    y.ToString();
}

bool Set(out int x) { x = 0; return true; }
```

This is an admittedly niche scenario, that compiles without error in the native compiler, but was broken in Roslyn in order to match the specification at the time. See [internal issue](#).

==/!= (relational equality operator) expressions

We introduce a new section [==/!= \(relational equality operator\) expressions](#).

The [general rules for expressions with embedded expressions](#) apply, except for the scenarios described below.

For an expression *expr* of the form `expr_first == expr_second`, where `==` is a [predefined comparison operator](#) or a [lifted operator](#), the definite assignment state of *v* after *expr* is determined by:

- If *expr_first* directly contains a null-conditional expression *E* and *expr_second* is a constant expression with value *null*, and the state of *v* after the non-conditional counterpart *E₀* is "definitely assigned", then the state of *v* after *expr* is "definitely assigned when false".
- If *expr_first* directly contains a null-conditional expression *E* and *expr_second* is an expression of a non-

nullable value type, or a constant expression with a non-null value, and the state of v after the non-conditional counterpart E_0 is "definitely assigned", then the state of v after $expr$ is "definitely assigned when true".

- If $expr_first$ is of type *boolean*, and $expr_second$ is a constant expression with value *true*, then the definite assignment state after $expr$ is the same as the definite assignment state after $expr_first$.
- If $expr_first$ is of type *boolean*, and $expr_second$ is a constant expression with value *false*, then the definite assignment state after $expr$ is the same as the definite assignment state of v after the logical negation expression `!expr_first`.

For an expression $expr$ of the form `expr_first != expr_second`, where `!=` is a [predefined comparison operator](#) or a [lifted operator](#), the definite assignment state of v after $expr$ is determined by:

- If $expr_first$ directly contains a null-conditional expression E and $expr_second$ is a constant expression with value *null*, and the state of v after the non-conditional counterpart E_0 is "definitely assigned", then the state of v after $expr$ is "definitely assigned when true".
- If $expr_first$ directly contains a null-conditional expression E and $expr_second$ is an expression of a non-null value type, or a constant expression with a non-null value, and the state of v after the non-conditional counterpart E_0 is "definitely assigned", then the state of v after $expr$ is "definitely assigned when false".
- If $expr_first$ is of type *boolean*, and $expr_second$ is a constant expression with value *true*, then the definite assignment state after $expr$ is the same as the definite assignment state of v after the logical negation expression `!expr_first`.
- If $expr_first$ is of type *boolean*, and $expr_second$ is a constant expression with value *false*, then the definite assignment state after $expr$ is the same as the definite assignment state after $expr_first$.

All of the above rules in this section are commutative, meaning that if a rule applies when evaluated in the form `expr_second op expr_first`, it also applies in the form `expr_first op expr_second`.

Remarks

The general idea expressed by these rules is:

- if a conditional access is compared to `null`, then we know the operations definitely occurred if the result of the comparison is `false`
- if a conditional access is compared to a non-null value type or a non-null constant, then we know the operations definitely occurred if the result of the comparison is `true`.
- since we can't trust user-defined operators to provide reliable answers where initialization safety is concerned, the new rules only apply when a predefined `==` / `!=` operator is in use.

We may eventually want to refine these rules to thread through conditional state which is present at the end of a member access or call. Such scenarios don't really happen in definite assignment, but they do happen in nullable in the presence of `[NotNullWhen(true)]` and similar attributes. This would require special handling for `bool` constants in addition to just handling for `null` /non-null constants.

Some consequences of these rules:

- `if (a?.b(out var x) == true)) x() else x();` will error in the 'else' branch
- `if (a?.b(out var x) == 42)) x() else x();` will error in the 'else' branch
- `if (a?.b(out var x) == false)) x() else x();` will error in the 'else' branch
- `if (a?.b(out var x) == null)) x() else x();` will error in the 'then' branch
- `if (a?.b(out var x) != true)) x() else x();` will error in the 'then' branch
- `if (a?.b(out var x) != 42)) x() else x();` will error in the 'then' branch
- `if (a?.b(out var x) != false)) x() else x();` will error in the 'then' branch
- `if (a?.b(out var x) != null)) x() else x();` will error in the 'else' branch

is operator and is pattern expressions

We introduce a new section `is operator and is pattern expressions`.

For an expression *expr* of the form `E is T`, where *T* is any type or pattern

- The definite assignment state of *v* before *E* is the same as the definite assignment state of *v* before *expr*.
- The definite assignment state of *v* after *expr* is determined by:
 - If *E* directly contains a null-conditional expression, and the state of *v* after the non-conditional counterpart *E₀* is "definitely assigned", and `T` is any type or a pattern that does not match a `null` input, then the state of *v* after *expr* is "definitely assigned when true".
 - If *E* directly contains a null-conditional expression, and the state of *v* after the non-conditional counterpart *E₀* is "definitely assigned", and `T` is a pattern that matches a `null` input, then the state of *v* after *expr* is "definitely assigned when false".
 - If *E* is of type boolean and `T` is a pattern which only matches a `true` input, then the definite assignment state of *v* after *expr* is the same as the definite assignment state of *v* after *E*.
 - If *E* is of type boolean and `T` is a pattern which only matches a `false` input, then the definite assignment state of *v* after *expr* is the same as the definite assignment state of *v* after the logical negation expression `!expr`.
 - Otherwise, if the definite assignment state of *v* after *E* is "definitely assigned", then the definite assignment state of *v* after *expr* is "definitely assigned".

Remarks

This section is meant to address similar scenarios as in the `== / !=` section above. This specification does not address recursive patterns, e.g. `(a?.b(out x), c?.d(out y)) is (object, object)`. Such support may come later if time permits.

Additional scenarios

This specification doesn't currently address scenarios involving pattern switch expressions and switch statements. For example:

```
_ = c?.M(out object obj4) switch
{
    not null => obj4.ToString() // undesired error
};
```

It seems like support for this could come later if time permits.

There have been several categories of bugs filed for nullable which require we essentially increase the sophistication of pattern analysis. It is likely that any ruling we make which improves definite assignment would also be carried over to nullable.

<https://github.com/dotnet/roslyn/issues/49353>

<https://github.com/dotnet/roslyn/issues/46819>

<https://github.com/dotnet/roslyn/issues/44127>

Drawbacks

It feels odd to have the analysis "reach down" and have special recognition of conditional accesses, when typically flow analysis state is supposed to propagate upward. We are concerned about how a solution like this could intersect painfully with possible future language features that do null checks.

Alternatives

Two alternatives to this proposal:

1. Introduce "state when null" and "state when not null" to the language and compiler. This has been judged to be too much effort for the scenarios we are trying to solve, but that we could potentially implement the above proposal and then move to a "state when null/not null" model later on without breaking people.
2. Do nothing.

Unresolved questions

There are impacts on switch expressions that should be specified:

AsyncMethodBuilder override

12/28/2021 • 8 minutes to read • [Edit Online](#)

Summary

Allow per-method override of the async method builder to use. For some async methods we want to customize the invocation of `Builder.Create()` to use a different *builder type*.

```
[AsyncMethodBuilderAttribute(typeof(PoolingAsyncValueTaskMethodBuilder<>))] // new usage of
AsyncMethodBuilderAttribute type
static async ValueTask<int> ExampleAsync() { ... }
```

Motivation

Today, async method builders are tied to a given type used as a return type of an async method. For example, any method that's declared as `async Task` uses `AsyncTaskMethodBuilder`, and any method that's declared as `async ValueTask<T>` uses `AsyncValueTaskMethodBuilder<T>`. This is due to the `[AsyncMethodBuilder(Type)]` attribute on the type used as a return type, e.g. `ValueTask<T>` is attributed as `[AsyncMethodBuilder(typeof(AsyncValueTaskMethodBuilder<>))]`. This addresses the majority common case, but it leaves a few notable holes for advanced scenarios.

In .NET 5, an experimental feature was shipped that provides two modes in which `AsyncValueTaskMethodBuilder` and `AsyncValueTaskMethodBuilder<T>` operate. The on-by-default mode is the same as has been there since the functionality was introduced: when the state machine needs to be lifted to the heap, an object is allocated to store the state, and the async method returns a `ValueTask<T>` backed by a `Task<T>`. However, if an environment variable is set, all builders in the process switch to a mode where, instead, the `ValueTask<T>` instances are backed by reusable `IValueTaskSource<T>` implementations that are pooled. Each async method has its own pool with a fixed maximum number of instances allowed to be pooled, and as long as no more than that number are ever returned to the pool to be pooled at the same time, `async ValueTask<T>` methods effectively become free of any GC allocation overhead.

There are several problems with this experimental mode, however, which is both why a) it's off by default and b) we're likely to remove it in a future release unless very compelling new information emerges (<https://github.com/dotnet/runtime/issues/13633>).

- It introduces a behavioral difference for consumers of the returned `ValueTask<T>` if that `ValueTask` isn't being consumed according to spec. When it's backed by a `Task`, you can do with the `ValueTask` things you can do with a `Task`, like await it multiple times, await it concurrently, block waiting for it to complete, etc. But when it's backed by an arbitrary `IValueTaskSource`, such operations are prohibited, and automatically switching from the former to the latter can lead to bugs. With the switch at the process level and affecting all `async ValueTask` methods in the process, whether you control them or not, it's too big a hammer.
- It's not necessarily a performance win, and could represent a regression in some situations. The implementation is trading the cost of pooling (accessing a pool isn't free) with the cost of GC, and in various situations the GC can win. Again, applying the pooling to all `async ValueTask` methods in the process rather than being selective about the ones it would most benefit is too big a hammer.
- It adds to the IL size of a trimmed application, even if the flag isn't set, and then to the resulting asm size. It's possible that can be worked around with improvements to the implementation to teach it that for a given deployment the environment variable will always be false, but as it stands today, every `async ValueTask` method saw for example an ~2K binary footprint increase in aot images due to this option, and, again, that

applies to all `async ValueTask` methods in the whole application closure.

- Different methods may benefit from differing levels of control, e.g. the size of the pool employed because of knowledge of the method and how it's used, but the same setting is applied to all uses of the builder. One could imagine working around that by having the builder code use reflection at runtime to look for some attribute, but that adds significant run-time expense, and likely on the startup path.

On top of all of these issues with the existing pooling, it's also the case that developers are prevented from writing their own customized builders for types they don't own. If, for example, a developer wants to implement their own pooling support, they also have to introduce a brand new task-like type, rather than just being able to use `{Value}Task{<T>}`, because the attribute specifying the builder is only specifiable on the type declaration of the return type.

We need a way to have an individual async method opt-in to a specific builder.

Detailed design

Using AsyncMethodBuilderAttribute on methods

In `dotnet/runtime`, add `AttributeTargets.Method` to the targets for `System.Runtime.CompilerServices.AsyncMethodBuilderAttribute`:

```
namespace System.Runtime.CompilerServices
{
    /// <summary>
    /// Indicates the type of the async method builder that should be used by a language compiler:
    /// - to build the return type of an async method that is attributed,
    /// - to build the attributed type when used as the return type of an async method.
    /// </summary>
    [AttributeUsage(AttributeTargets.Method | AttributeTargets.Class | AttributeTargets.Struct |
        AttributeTargets.Interface | AttributeTargets.Delegate | AttributeTargets.Enum, Inherited = false,
        AllowMultiple = false)]
    public sealed class AsyncMethodBuilderAttribute : Attribute
    {
        /// <summary>Initializes the <see cref="AsyncMethodBuilderAttribute"/>.</summary>
        /// <param name="builderType">The <see cref="Type"/> of the associated builder.</param>
        public AsyncMethodBuilderAttribute(Type builderType) => BuilderType = builderType;

        /// <summary>Gets the <see cref="Type"/> of the associated builder.</summary>
        public Type BuilderType { get; }
    }
}
```

This allows the attribute to be applied on methods or local functions or lambdas.

Example of usage on a method:

```
[AsyncMethodBuilder(typeof(PoolingAsyncValueTaskMethodBuilder<>))] // new usage, referring to some custom
builder type
static async ValueTask<int> ExampleAsync() { ... }
```

It is an error to apply the attribute multiple times on a given method.

It is an error to apply the attribute to a lambda with an implicit return type.

A developer who wants to use a specific custom builder for all of their methods can do so by putting the relevant attribute on each method.

Determining the builder type for an async method

When compiling an async method, the builder type is determined by:

1. using the builder type from the `AsyncMethodBuilder` attribute if one is present,
2. otherwise, falling back to the builder type determined by previous approach. (see [spec for task-like types](#)).

If an `AsyncMethodBuilder` attribute is present, we take the builder type specified by the attribute and construct it if necessary.

If the override type is an open generic type, take the single type argument of the async method's return type and substitute it into the override type.

If the override type is a bound generic type, then we produce an error.

If the async method's return type does not have a single type argument, then we produce an error.

We verify that the builder type is compatible with the return type of the async method:

1. look for the public `Create` method with no type parameters and no parameters on the constructed builder type.
It is an error if the method is not found. It is an error if the method returns a type other than the constructed builder type.
2. look for the public `Task` property.
It is an error if the property is not found.
3. consider the type of that `Task` property (a task-like type):
It is an error if the task-like type does not matches the return type of the async method.

Note that it is not necessary for the return type of the method to be a task-like type.

Execution

The builder type determined above is used as part of the existing async method design.

For example, today if a method is defined as:

```
public async ValueTask<T> ExampleAsync() { ... }
```

the compiler will generate code akin to:

```
[AsyncStateMachine(typeof(<ExampleAsync>d__29))]
[CompilerGenerated]
static ValueTask<int> ExampleAsync()
{
    <ExampleAsync>d__29 stateMachine;
    stateMachine.<>t__builder = AsyncValueTaskMethodBuilder<int>.Create();
    stateMachine.<>1__state = -1;
    stateMachine.<>t__builder.Start(ref stateMachine);
    return stateMachine.<>t__builder.Task;
}
```

With this change, if the developer wrote:

```
[AsyncMethodBuilder(typeof(PoolingAsyncValueTaskMethodBuilder<>))] // new usage, referring to some custom
builder type
static async ValueTask<int> ExampleAsync() { ... }
```

it would instead be compiled to:

```
[AsyncStateMachine(typeof(<ExampleAsync>d__29))]
[CompilerGenerated]
[AsyncMethodBuilder(typeof(PoolingAsyncValueTaskMethodBuilder<>))] // retained but not necessary anymore
static ValueTask<int> ExampleAsync()
{
    <ExampleAsync>d__29 stateMachine;
    stateMachine.<>t__builder = PoolingAsyncValueTaskMethodBuilder<int>.Create(); // <>t__builder now a
different type
    stateMachine.<>1__state = -1;
    stateMachine.<>t__builder.Start(ref stateMachine);
    return stateMachine.<>t__builder.Task;
}
```

Just those small additions enable:

- Anyone to write their own builder that can be applied to async methods that return `Task<T>` and `ValueTask<T>`
- As "anyone", the runtime to ship the experimental builder support as new public builder types that can be opted into on a method-by-method basis; the existing support would be removed from the existing builders. Methods (including some we care about in the core libraries) can then be attributed on a case-by-case basis to use the pooling support, without impacting any other unattributed methods.

and with minimal surface area changes or feature work in the compiler.

Note that we need the emitted code to allow a different type being returned from `Create` method:

```
AsyncPooledBuilder _builder = AsyncPooledBuilderWithSize4.Create();
```

Note that this mechanism to change the the builder type cannot be used when the synthesized entry-point for top-level statements is async. An explicit entry-point should be used instead.

Drawbacks

- The syntax for applying such an attribute to a method is verbose. The impact of this is lessened if a developer can apply it to multiple methods en mass, e.g. at the type or module level.

Alternatives

- Implement a different task-like type and expose that difference to consumers. `ValueTask` was made extensible via the `IValueTaskSource` interface to avoid that need, however.
- Address just the `ValueTask` pooling part of the issue by enabling the experiment as the on-by-default-and-only implementation. That doesn't address other aspects, such as configuring the pooling, or enabling someone else to provide their own builder.
- Earlier versions of this document allowed for scoped override of builder types.

Unresolved questions

1. **Replace or also create.** All of the examples in this proposal are about replacing a buildable task-like's builder. Should the feature be scoped to just that? Or should you be able to use this attribute on a method with a return type that doesn't already have a builder (e.g. some common interface)? That could impact overload resolution.
2. **Private Builders.** Should the compiler support non-public async method builders? This is not spec'd today, but experimentally we only support public ones. That makes some sense when the attribute is applied to a type to control what builder is used with that type, since anyone writing an async method with that type as

the return type would need access to the builder. However, with this new feature, when that attribute is applied to a method, it only impacts the implementation of that method, and thus could reasonably reference a non-public builder. Likely we will want to support library authors who have non-public ones they want to use.
